Forty-four years ago, Sir Ernest Kennaway and his colleagues identified, for the first time, a pure chemical that was capable of causing cancer in animals, and a year later isolated another from material that was widespread in the environment. At that time, and even after these crucial observations, it was commonly assumed that cancers were an inevitable accompaniment of ageing and that little could be done to reduce the mortality they caused. It is now clear, however, that most, if not all cancers have environmental causes and can in principle be prevented. The identification of environmental hazards and clarification of the mechanisms through which they cause disease are thus among the highest priorities in cancer research.

Since Kennaway's seminal work[1,2], the evidence that cancer can be prevented has accumulated steadily and is now overwhelming. Whether it will ever be possible to prevent the disease altogether, as we can now prevent poliomyelitis and scurvy, is impossible to say until we know more about the mechanism by which it is produced; but we should be able to reduce the age-specific incidence rates—which account for a quarter of all deaths of men in Britain under 75 years of age—by at least 80 to 90%. That this is so, is suggested primarily by the great variation in the incidence of different types of cancer in different communities and in different parts of the world.

This variation is illustrated in Tables 1 and 2, which show maximum and minimum incidence rates for all cancers that are common enough somewhere for the disease to affect more than 1% of men or women by 75 yr, in the absence of other causes of death. The range of variation is never less than fourfold and is sometimes more than a hundredfold. I have presented the data as cumulative incidence rates up to 75 yr, despite the fact that rates at old ages tend to be unreliable where personal medical services are sparse, to illustrate how common some cancers can become in countries like our own where half the population lives to be over that age. In estimating the range of variation, however, I have limited comparison to ages under 65 yr.

With rare cancers, the very fact of their rarity makes the demonstration of their incidence in the small populations that have been studied outside the industrialised countries extremely difficult, if not impossible. Nevertheless, some clearly vary; for example, Burkitt's lymphoma, which never affects more than 1 in 1,000 people[3], varies at least 100-fold. Others, such as acute leukaemia in young adults and nephroblastoma in children, seem to be fairly constant everywhere.

Some of this variation is, of course, genetic in origin. That heredity is not the principal cause is, however, shown by migrant groups, whose experience of disease usually changes when they change their way of life in a new country, and by the variation in the incidence of cancer with time. The latter can seldom be demonstrated conclusively, partly because it is difficult to compare the efficiency of case finding at different periods, and partly because a high standard of case registration has obtained in only a few places for more than 10 yr—the most notable being Denmark and Connecticut, USA. We have, therefore, to rely to a large extent on trends in mortality, which may also be influenced by changes in the efficacy of treatment.

Nevertheless, some changes are so gross that it is impossible to doubt that there has been a real change in incidence: for example, the increase in lung cancer in all developed countries, the increase in oesophageal cancer in the black population of South Africa, and the decrease in gastric cancer in the USA. Many lesser changes have taken place in Britain during the last 20 years. These are shown in Table 3, which lists all those cancers for which the mortality rate, standardised for age, has changed by more than one per cent a year between 1958 and 1973. Several of these changes cannot be dismissed as artefacts, because the disease is easy to diagnose and the death rate has increased despite improving treatment (as with melanoma and cancer of the testis). Taken altogether, the evidence suggests that all common cancers have varied in incidence from time to time, just as they now vary from place to place.

Much of this variation can now be attributed to the action of specific agents. Indeed, so many are now known that we may reasonably hope to extrapolate from past experience in seeking others. I shall, therefore, begin by reviewing briefly the known agents and the ways in which they have been detected.

Iatrogenic hazards

About a score have been prescribed by doctors (Table 4). Most have caused only a few cases and their effect has been apparent to clinicians and pathologists because the microscopic appearance of the tumour or the site in which it occurred was so unusual. Examples include adenocarcinoma of the vagina in young women whose mothers had taken stilboestrol during the relevant pregnancy (recognised when a lift broke down in Boston and the paths of a gynaecologist and a pathologist crossed for sufficiently long for them to exchange experiences); angiosarcoma of the liver and spleen following the injection of thorotrast; squamous carcinoma of the thigh following the local application of coal tar ointment; squamous carcinoma of the

palm of the hands associated with arsenicism; reticulosarcoma of the brain following immunosuppression to prevent rejection of a renal transplant; and a peculiar type of liver tumour in women using steroid contraceptives.

The only known agents in this group that have caused any substantial number of cancers have been ionising radiations, which probably caused between 5 and 10% of all childhood cancers in Western Europe and North America during the 1950s and 60s, when used for diagnosis during the pregnancy of the mother; and oestrogens, prescribed for post-menopause women, which may account for much of the recent increase in the incidence of endometrial cancer in the USA. In both cases, the risks were overlooked for a long time, because the tumours did not differ in any obvious way from the tumours that occurred quite commonly as a result of other causes, and they were eventually detected only after large scale case-control studies had been carried out with the object of investigating the role of the agents in the aetiology of the particular disease[1-4].

Despite the number of tumours caused by these last two agents, the total number of cases that are iatrogenic in origin is much less than readers of Illich's *Medical Nemesis* might suspect and cannot have constituted more than a minute proportion of the total impact of cancer on society.

Occupational hazards

Other agents have caused hazards in a wide variety of occupations. These are listed in Tables 5 and 6. In three instances the risks were discovered after the agents (4-aminobiphenyl, mustard gas and vinyl chloride) had been shown to cause cancer in animals. Other agents were discovered incidentally in the course of investigating other industrial hazards, as in the case of cancer of the prostate in cadmium workers and cancer of the lung in rubber workers. Most, however, were discovered because the interest of a clinician, an epidemiologist, or a pathologist was aroused by the observation of a cluster of cases that seemed too large to be easily attributable to chance. Sometimes these clusters have been quite small, as when Dr John Jones reported that he was disquieted to have seen two employees of the Mond Nickel Company develop nasal sinus cancer within a year. Often, however, the risk has been overlooked for a long time, particularly when the same type of cancer was common in the general population as a result of other causes.

Like the iatrogenic hazards, these occupational ones cannot have been responsible for more than a very small proportion of all cancers, as the total number of men who have been exposed in the course of their work, other than open air workers exposed to ultraviolet light and, to a lesser extent, the wide variety of workers exposed to asbestos, is small in proportion to the population as a whole. They are important, however, for two reasons.

First, they are important to the workers concerned who have had a 50% risk of developing the disease in some industries. Indeed, in one small group of 19 men employed on distilling 2-naphthylamine, the risk proved to be 100%, 18 dying of bladder cancer and the last having been killed in an accident shortly after the disease was diagnosed. Second, some of the agents concerned have found their way into the general environment, so that millions of people have been exposed to them unintentionally and sometimes in an uncontrolled way. These agents are listed in Table 6. It is easy enough to dismiss the corresponding risks on the grounds that the doses are minute; but we can no longer assume that thresholds exist for chemical or physical agents and we ought neither to ignore nor to condemn them until we have derived quantitative relationships between the dose to which individuals are exposed and the resultant incidence of the disease. At present we can do this only very crudely. Nevertheless, any quantitative evidence is better than none.

Industrial pollution

Consider, for example, polycyclic hydrocarbons and asbestos. For the first, we have evidence that the large amount of benzo(*a*)pyrene inspired by gas retort house workers produced a risk of lung cancer only about 80%

Table 2 Range of variation in the incidence of common cancers in men (unless specified ♀)

†At ages 35–64 yr.

greater than the national average[8]. Since the residents of large towns are unlikely to have been exposed to more than one-hundredth of that amount—mainly from the combustion of domestic coal[9]—the contribution of these agents to the urban excess of the disease is unlikely to have been large, a conclusion that is confirmed by the low incidence of the disease in non-smokers irrespective of where they live.

As for asbestos, we know that it reaches the ambient air from a variety of sources, including the clothes of asbestos workers. These were presumably the principal source of exposure of the 37 men and women in nine countries who are reported to have developed mesothelioma of the pleura after being household contacts of asbestos workers[10]. The maximum concentration that has been found in the air near building sites where asbestos was being sprayed is, however, three orders of magnitude less than that which has been regarded as an acceptable concentration in the asbestos industry[11], and the amount that is commonly present in town air is still less by another two orders of magnitude. Unfortunately, we are still uncertain about the size of the risk that is associated with this accepted concentration of about 0.1 mg m^{-3}. In one study of an asbestos textile factory in England[12], it was found that the relative risk of lung cancer for men who had been employed for 20 yr decreased progressively from 10 times 'normal', if they had been employed for at least 10 years before 1933 (that is, the date when some control of asbestos dust in the air of factories first became effective in the UK), to 3½ times normal if they had been employed before 1933, but for less than 10 years, to 1½ times normal if they had first been employed only after 1933. Few men who were first employed only after 1951 have yet been employed for 20 yr, but preliminary estimates (which are highly unreliable because the number of men observed is so small) suggest that some risk may still have persisted since that date. Detailed dust records were not obtained in the early years in a way that enables them to be compared with present data, but the amount of dust in the air was initially gross and continued to be much greater than at present for some time after 1933. Even in 1951, the mean dust level to which men were exposed is likely to have been 3½ times greater than it is now, and we shall have to wait for many years before industrial data enable us to make a reasonable estimate of the possible risk associated with an average exposure up to 0.1 mg m^{-3} during normal working life.

Table 3 Changing mortality rates from different cancers* (England and Wales, 1958 to 1973)

Type of cancer	(%) Change	
	Males	Females
Melanoma	+95	+47
Myelomatosis	+65	+70
Lung	+29	+94
Pancreas	+19	+20
Testis	+19	
Oesophagus	+16	+17
Stomach	−25	−34
Buccal cavity	−38	−24
Cervix		−23

*All cancers with rate of change equal to or more than 1 % per year.

Measurements like these exculpate individually as major contributors to the gross variation in cancer incidence between countries all the agents that are known to cause specific occupational hazards (other than ultraviolet light), whether acting within industry or as pollutants in the general environment. In so far as we can explain this variation, it seems rather to be due to differences in social behaviour, diet and the opportunity for infection.

Table 4 Iatrogenic causes of cancer

Agent	Site of cancer
Diagnostic or therapeutic X rays	All sites
Thorium	Bone
Thorotrast	Liver, spleen marrow (leukaemia)
Polycyclic hydrocarbons in coal tar ointments	Skin
Alkylating agents	
Melphalan, cyclophosphamide	Marrow (leukaemia)
Oestrogens	Endometrium, breast (M) ? breast (F)
Stilboestrol (transplacental)	Vagina
Steroid contraceptives	Liver
Androgens (anabolic steroids)	Liver
Arsenic	Skin, lung
Chlornaphazine	Bladder
Immunosuppressive drugs	Reticulosarcoma
Phenacetin	?Renal pelvis

Other hazards

The other agents that are known to cause cancer are listed in Table 7. The number is small, but the cancers that have been produced are legion. Cancers of the buccal cavity attributable to chewing, for example, account for a quarter of all cancers in men in parts of India, while cancers of the lung attributable to smoking account for more than a third of all lethal cancers in men in Britain.

One agent, aflatoxin, was discovered to be a powerful carcinogen as a result of an outbreak of poisoning that killed 100,000 ducks and turkeys in British farms. The outbreak was traced to a consignment of peanut meal contaminated with *Aspergillus flavus* which produced a metabolite that not only caused acute liver failure in poultry, but also caused cancer of the liver in minute doses in a wide variety of animals[13,14]. Human liver cells contain the enzymes necessary to produce the active agents (the epoxy-metabolites of aflatoxin), and *Aspergillus flavus* is a frequent contaminant of foodstuffs stored under hot and humid conditions. Now it has been shown that the incidence of liver cancer in Thailand, Singapore, Kenya, Swaziland and Mozambique is proportional to the amount of aflatoxin in the diet[15,16]. The vagaries of daily diet make it unlikely that we shall ever be able to establish the relationship in individuals; but the total evidence is strong enough to justify an attempt to prevent the disease by reducing exposure. Unfortunately, this will not be easy, as fungal contamination is difficult to avoid under the conditions in which the staple foods are commonly stored in the tropics, and it will be expensive to substitute alternative methods.

The other agents listed in Table 7 were, for the most part, discovered as a result of clinical acumen dating back

nearly 200 years to Soemmerung's description of lip cancers in pipe smokers[17]. Clinical associations, however, tend to be overlooked if the conclusions suggested are socially unacceptable, and little attention was paid to the possible effects of smoking until the death rate from lung cancer in men had increased 25-fold (Fig. 1). The conference that was called by the Medical Research Council in 1947 could not decide whether the increase was real or an artefact due to improved diagnosis, but it did recommend a study to seek a possible cause. The subsequent enquiry showed that patients with lung cancer tended to smoke more than other patients, and within 3 years it was possible to conclude from the human evidence alone that cigarette smoking was a cause of the disease[18]. Whether these observations, or any others that are both practicable and ethical to obtain, can be regarded as constituting logical proof that a carcinogenic agent has been detected is debatable and is not of great interest. What is of interest is whether the evidence justifies an attempt at prevention and, if so, whether removal of the agent is followed by the result we seek[19].

Prevention should, of course, ideally be carried out in a controlled way with random allocation of individuals, or groups of individuals, to experimental and control series. In practice, however, this is seldom possible as the experiment is likely to require the cooperation of a large number of people who have to be convinced that it will be successful before it can be begun. Everyone, therefore, will want to be in the experimental group. This is what has always happened in industry; but when the disease disappears, as so many occupational cancers have, few people have challenged the logic that led to the intervention.

Once smoking began to be studied seriously as a cause of cancer, data were soon collected that confirmed the old clinical observation of a relationship with cancer of the mouth, and there are now strong grounds for believing that it also causes many cancers of the pharynx, larynx and oesophagus. Weaker, but consistent, evidence—like that summarised in Table 8—also suggests that it may play a part in producing cancers of the bladder and pancreas.

That alcohol contributes to the causation of a large proportion of cases of cancer of the oesophagus, and to a somewhat smaller proportion of cancers of the mouth, pharynx and larynx, in some countries, has been suspected ever since the mortality from these cancers was found to be unusually high in publicans, waiters and others employed in alcoholic trades[20]. The subject has, however, proved so unattractive to research workers that we still do not even know whether it is the alcohol itself that is responsible (possibly by solubilising a specific agent) or whether it is another component of alcoholic drinks that may vary in amount from one drink to another. That the subject has been unpopular may have been because pure alcohol is not carcinogenic to laboratory animals or because the amount consumed by the individual is difficult to assess with accuracy—or even because of a natural aversion for investigating such an unpopular subject. Interest in it has, however, been revived and studies are now being carried out on oesophageal cancer in parts of France where the characteristic alcoholic drinks are cider and cider-based liqueurs[21]. If, however, alcoholic drinks are important in the aetiology of cancers of the upper digestive tract in Europe and North America, they certainly do not explain the astronomical figures for the incidence of the disease in central Asia, where very little alcohol is consumed.

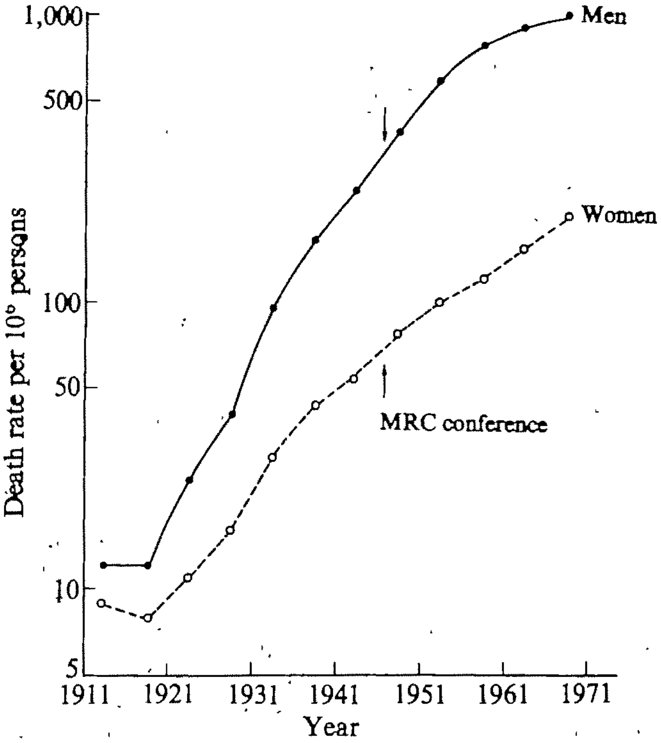

Fig. 1 Trend in crude death rate from lung cancer 1911–1971, by sex, showing state at time of MRC conference.

Viruses

Another potential hazard is infection with an oncogenic virus, but it is still an open question whether viruses can ever cause cancer in man. Direct evidence of case-to-case infection is extremely weak—no-one, for example, who has used adequate controls has been able to repeat Vianna, Greenwald and Davies's[22] observation that patients with Hodgkin's disease have had unusually close personal contact—and the laboratory evidence that cancers are associated with viral infection is open to several interpretations.

Table 7 Other environmental causes of cancer

'Agent'	Site of cancer
Sunlight	Exposed skin (rodent ulcer, squamous carcinoma, ? melanoma)
Associated with use of 'Kangri' and 'dhoti'	Skin of abdomen, groin, and thigh (squamous carcinoma)
'Reverse smoking'	Palate
Chewing betel, tobacco, lime	Mouth
Smoking	Mouth, pharynx, larynx, bronchus, oesophagus, bladder, ? pancreas
Aflatoxin	Liver
Schistosomiasis	Bladder
Associated with sexual intercourse	Cervix uteri

Table 8 Risk of death from cancer of pancreas in continuing cigarette smokers relative to life-long non-smokers (prospective studies)

Population*	Sex	Risk compared with that in non-smokers: Cigarette smokers	Current cigarette smokers smoking per day: 1–9	10–20	21–39	40 or more

*Numbers of deaths in parentheses: for details see Hammond[20], Kahn[21], Department of National Health and Welfare[22], Cederlof *et al.*[23] and Doll and Peto[19].

Consider, for example, the extensive evidence that now connects the EB virus with Burkitt's lymphoma and carcinoma of the nasopharynx. In epidemic areas these diseases occur nearly always in individuals infected by the virus. Viral DNA is present in all the tumour cells and determines the expression in them of virus-coded neoantigens; and virus production can be activated in some of the tumour cells in the laboratory. The EB virus is widespread in human society and is the cause of infectious mononucleosis, when it stimulates the proliferation of mononuclear cells of the lymphatic series. *In vitro*, it confers the property of continuous growth on normal human B lymphocytes in culture, in a way that is analogous to malignant transformation. Finally, it has been shown to cause malignant lymphomas in South American cotton top marmosets on experimental inoculation.

What more can laboratory investigation be expected to do? The International Agency for Research on Cancer[26] is attempting to relate the development of the disease to new infection by following up children in the West Nile district of Uganda from whom blood samples have been taken for serum studies; but the results are unlikely to be decisive if, as one suspects, viral infection is only one of several conditions necessary for the development of the disease. If this turns out to be so, the only remaining approach will be to develop a vaccine that can be shown to prevent the disease[27] —immensely difficult though that must be—and the same would also be true if cervix cancer were firmly linked to infection with the type II herpes simplex virus or to any other infective agent.

That cervix cancer is venereal in origin is now virtually certain. We know that the disease spares nuns and is most common in prostitutes; that the risk increases with the number of marriages and with the age at which coitus first occurs, but not with the number of pregnancies, nor with the frequency of intercourse within marriage; and that more of the husbands of affected women have had extramarital intercourse than of the husbands of control women[28–30]. To these facts we can add Beral's observation[31] that the mortality from cervix cancer in cohorts of women of different ages varies with the incidence of gonorrhoea at the time they were 20 years old, and the accumulating evidence that obstructive methods of contraception are protective[32].

Interaction of agents

If viruses do, in fact, cause cancer, they may do so only by interacting with other factors, and this may account for the separate correlation of hepatitis B antigen and aflatoxin with hepatoma and of the EB virus and gross malarial infection with Burkitt's lymphoma. That two different agents may interact to produce cancer has been established by occupational studies which have demonstrated interactions between smoking and asbestos and smoking and ionising radiations and have provided quantitative data like those on the incidence of lung cancer in uranium miners in the USA[33].

Similar data are now also being obtained by the International Agency for Research on Cancer[26] for the interaction between tobacco and alcohol in the production of oesophageal cancer in France. Preliminary estimates, based on a retrospective case-control study of patients and a random sample of the population, suggest that the risk of developing the disease increases both with the amount smoked and with the amount drunk, until among men who drink 81 or more grams of ethyl alcohol (equivalent to 7 whiskies) and smoke 20 or more cigarettes a day, the risk is 45 times that in those continent men who drink less than 40 grams and smoke less than 10 cigarettes a day.

The existence of such interactions, which has been suspected since the early experiments of Rous and Kidd[34] and Berenblum and Shubik[35], can be of great importance. For they may provide not only the explanations for apparently conflicting observations, but also alternative means of preventing disease, one of which may be more practicable than the other. If, for example, smoking and asbestos interact to produce bronchial cancer, there may be no point in trying to give quantitative labels to their respective shares. Both may be responsible for producing more than half the cases in the sense that the elimination of either would reduce the total risk by more than 50%. The important conclusion is that we can break the chain of causation at either of two links, and it may be as idle to try and partition responsibilities as it is to try to quantify the relative contributions of nature and nurture to disease in general.

Strategy for detection

In this incomplete review, I have sought to provide an account of the hazards of cancer to man and to use the experience of the past to indicate how other hazards can be detected in the future. We cannot, of course, hope to detect hazards efficiently until we know how cancer is produced, so that a policy for detection must include the support of basic biological research. Success in this field is dependent on the development of ideas and is difficult to foster except by providing the conditions in which outstanding investigators are able to give full rein to their imagination.

Test of products before use

Two types of hazard stand out as socially unacceptable, although they are relatively unimportant numerically: that is, the hazards associated with occupation and the use of prescribed drugs. The evidence that chemical carcinogens, or their reactive metabolites, are commonly electrophilic, react with DNA and, in consequence, are able to induce mutations, has suggested that it may be possible to predict carcinogenicity by relatively quick and simple tests with bacteria. It is not certain that any one test, or combination of tests, will prove to be adequate, but preliminary results are encouraging[36].

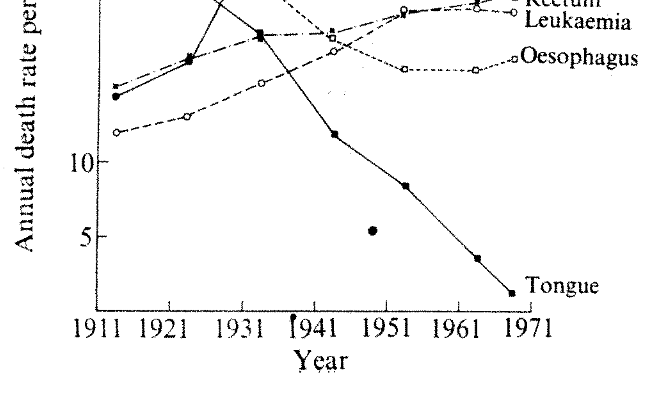
This, however, will not absolve us from making arrangements to detect hazards to man. Not only must we expect some chemicals to escape the net, particularly if they are hormones or act as promoters, enzyme inducers, or repair inhibitors; but we shall also wish to use some, and possibly many, substances that give positive results in animals, if the benefits are judged to be great enough to outweigh the harm. The continuing challenge to laboratory scientists is to discover enough about metabolism and the mechanisms of carcinogenesis in man to enable us to predict the extent of the hazard if the substance is used in a particular way. Meanwhile, we must either refrain from introducing such immensely useful materials as phenobarbitone, isoniazid, DDT, saccharin, and the minute amounts of stilboestrol that are used to fatten cattle, although they do not have any detectable effect in man, or arrange to detect and quantify hazards to man at the earliest opportunity.

Record linkage

Embryo mechanisms suitable for this purpose already exist in Britain, that are based on the records of the National Health Service and the Office of Population Censuses and Surveys, and to a varying extent in other countries[37–40]. Identifying information about all people who develop cancer is already integrated into a single file in England and Wales, and we now need to create similar files of people who are exposed to different chemicals. The Registrar-General has begun to do this by maintaining a file of a 1% sample of the population which is up-dated at each successive census in respect of births, deaths, immigrants and emigrants, and by recording the cumulative occupational experience of the selected sample throughout their lives. This file can be linked within OPCS to the occurrence of cancer and so can provide an automatic assessment of the risks associated with any particular industry. It will be necessary, however, to increase the size of the sample to at least 10% before it will be of any value for any but the larger risks. Very little information is included about specific exposures and it will probably also be necessary to require industry to maintain records of all employees who are exposed to new chemicals, so that they can be checked periodically against the file of cancer cases. Similarly, if we are serious in our desire to control adverse reactions to drugs, including reactions like cancer which occur only infrequently or after a prolonged latent period, we shall have to introduce some system for recording drug usage such as Skegg[40] is now doing on a pilot scale in 20 practices, or possibly create a new category of drugs that can be prescribed only on special forms for a period after they are introduced. Data that identify the patients can then be stored in a computer for subsequent matching with similar data in the cancer index.

The concept of linking records by computer has given rise to anxiety lest they are used to the detriment of the individual, as has happened when personal records have been linked by credit organisations in the USA, and some doctors have been worried by the apparent loss of confidentiality. Confidentiality can, however, be protected in a computer much more easily than in the standard case-note, and I know of no instance where the provision of personal information to a bona fide medical research worker has been abused. It is, of course, for the public to decide; but in my experience, most people understand that we cannot protect them against disease unless we are allowed the necessary tools. Record linkage of the type required is, moreover, not expensive when the essential records have to be made for other purposes, as they now all are—the only defect of the present system being that the records are not organised in a way that enables them to be used to detect hazards to health.

Fig. 2 Trends in mortality from common cancers in men 1911–1971, standardised for age.



Cancer incidence and mortality rates

Record linkage is less useful as a means of detecting hazards arising from environmental pollution or household materials, if there is no greater human exposure at the source of their creation or manufacture. In these circumstances we can rely only on cancer and death registries to arouse suspicion by revealing changes in the incidence of disease with time or place. Such registries are, also, one of our principal weapons for obtaining clues to other hazards that are not iatrogenic, occupational or attributable to pollution and which account for the mass of cancers that fill our hospitals today. Death rates for most of these and other cancers that were common between 1911 and 1970 are shown in Figs 2 and 3. The rates have been standardised for age and are limited to ages under 65 years, as diagnostic services for old people were so much less effective in the earlier part of the period. All the trends must have been affected by changing diagnostic standards and many will also have been affected by improving treatment, but we cannot avoid the conclusion, which accords with clinical experience, that cancers of the stomach, colon and rectum, and cancers of the breast and uterus (though not of the ovaries) have been common for many years so that if they are environmental in origin, as the evidence of geographical and social variation suggests, the responsible factors must have been prevalent at least before the beginning of the century.

Investigation of diet

One feature of the British way of life that has distinguished it from the Asiatic or African way for the appropriate length of time is its diet, and factors related to diet have been suspected of contributing to the production of cancer for many years. Until recently, however, there has been little precise evidence and very few promising ideas. Now, a spate of fresh ideas enables dietary factors to compete for the interest of research workers on almost equal terms with

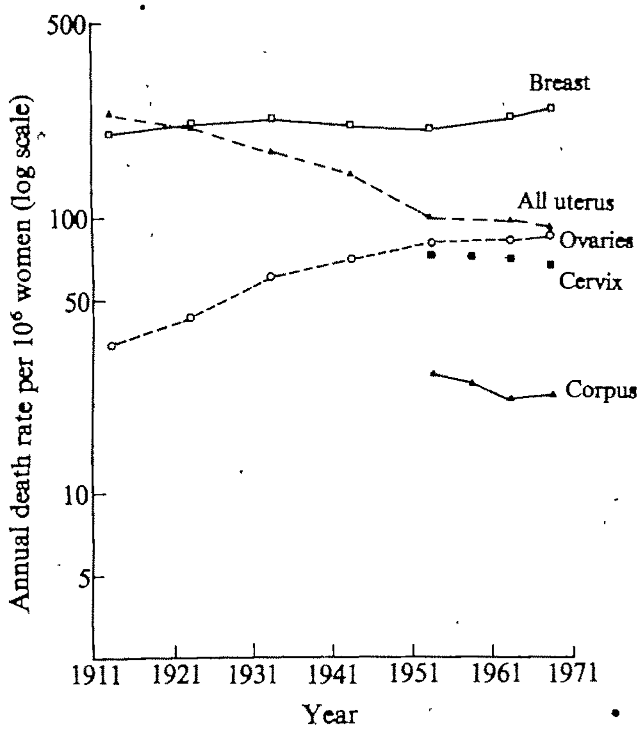


Fig. 3 Trends in mortality from common cancers of breast and genital tract in women, 1911–1971, standardised for age.

viruses and immune reactions. One such idea, to which I referred previously, was that aflatoxin might be responsible for tropical liver cancer. Another was the discovery that the cycad nut contained a constituent (cycasin) that was harmless in itself, but which gave rise to a carcinogen in the bowel of an animal with a normal intestinal flora. This was not fruitful in itself, but it focused interest on the possible role of intestinal bacteria and led Williams to examine the intestinal flora of people living in areas where the incidence rates of colon cancer were grossly different. Populations with a high risk were found to be characterised by the presence in their faeces of large numbers of anaerobic bacteria that were able to dehydrogenate bile acids, and Williams and his colleagues postulated that this might result in the production of carcinogens that acted locally on the colonic mucosa[41]. In 1975, Meade and his colleagues at Northwick Park, working in conjunction with Williams' group, reported the preliminary results of a retrospective study of patients with and without large bowel cancer which supported this idea[42], and these findings have now been confirmed in twice as many patients[43]. The original hypothesis will, however, have to be elaborated if it is to account for the low incidence of the disease in Finland and the increased incidence in the upper socio-economic classes in Hong Kong[43,44]; and Hill[43] suggests that it may also be necessary to have a high level of vitamin K to act as a hydrogen acceptor, before carcinogens can be formed under anaerobic conditions in the gut.

Burkitt's[45] hypothesis, that the relative lack of indigestible fibre in the diet of industrialised countries might be the primary cause of a variety of diseases of the large bowel that are absent in populations whose diet consists of natural unprocessed foods has also opened up new lines of thought. The greater bulk of faeces and the more rapid transit time associated with a high fibre diet could hardly account in physicochemical terms for the sort of gross differences in the incidence of large bowel cancer that occur between black African and the English-speaking countries; but the altered conditions in the bowel might perhaps account for the variation in the intestinal flora.

A fourth way in which diet may affect the incidence of cancer is by providing the raw materials from which nitrosamines are produced in the stomach—a group of powerful carcinogens that are still looking for human cancers to induce. Potential carcinogens of this group can be formed in acid gastric juice by the action of nitrites on secondary amines in food—the nitrites being present because of their use as preservatives, or because they were formed from nitrates in the mouth as a result of bacterial metabolism. This, however, is speculative. All we know for certain is that gastric cancer was common in the relatively poor populations of northern Europe and Japan (though not in most of the even poorer populations of Africa), that it has been becoming progressively less common in Western Europe and much less common in the USA, that it is less common in Japanese migrants to California and Hawaii than in the Japanese in Japan, and that the disease in the migrants tends to occur in those who eat pickled vegetables and dried and salted fish and not in those who eat such Western vegetables as tomatoes, celery, corn, lettuce and onion[46]. Could this be, as Weisburger and Wynder[47] suggest, because the small amounts of vitamin C inhibit the formation of nitrosamines in the stomach? Alternatively, it may be that the progressive reduction in incidence is due to better preservation of food, with a consequent reduction in the opportunity for bacterial or fungal contamination.

That vitamins may play a part in protecting against cancer is also suggested by experiments[48] on animals in which the incidence of cancer was reduced by a vitamin A-enriched diet. Now two sets of human data—one a prospective study of men with known dietary histories[49] and another a biochemical investigation of serum A levels in patients and controls[50], suggest that a deficiency of vitamin A may increase the risk of squamous cell carcinoma of the bronchus in cigarette smokers.

Fat also is a possible factor. Its consumption is closely correlated with the incidence of colon cancer ($r=0.78$) and breast cancer ($r=0.79$) in different countries, and several investigators have suggested that its content in the diet may directly affect the incidence of these diseases[51,52]. Armstrong[53] recently pointed out that the incidence of endometrial cancer was even more closely correlated with dietary fat ($r=0.85$) and showed that excess consumption of fat could account for five of the clinical characteristics that tend to be associated with the development of this disease; that is, obesity, early menarche, late menopause, maturity onset diabetes, and hypertension. Virtually all oestrogen produced in post-menopausal women is derived from oestrone which, in turn, is produced by aromatisation of the androstenedione secreted by the adrenals. Fat could play a part either because androstenedione is converted to oestrone in adipose tissue[54] or, perhaps, by inducing the oxidase systems that metabolise pre-carcinogens.

Conclusion

I have concluded by referring to some of the hazards that may be associated with diet, not because I believe that their existence has been proved, but because they provide an indication of the way in which the hazards that are responsible for the majority of human cancers may be detected in the future; that is, by a combination of epidemiological and laboratory enquiries. Such studies were often conducted independently in the past, with very little contact between the research workers involved. The position was, however, transformed when the World Health Organization set up the International Agency for Research on Cancer with the explicit purpose of encouraging such collaboration internationally, and it has been further strengthened in this country now that the Cancer Research Campaign, the Imperial Cancer Research Fund and the Department of Health and Social Security have joined the Medical Research Council in establishing academic units of cancer epidemiology within, or in close association with, the major departments of basic cancer research. With this collaboration, a rational use of medical records, and continued support for general biological research, I see no reason why causes for the remaining common cancers should not be detected within one or two decades. That is not to say that it will be easy to prevent the disease. For if, as I suspect, these hazards are associated with the common diet of developed countries, the problems that we are now having to face in preventing tobacco-induced cancer will seem childishly simple.

Rapidly-formed ferromanganese deposit from the eastern Pacific Hess Deep

William C. Burnett*
Department of Earth and Space Sciences, State University of New York, Stony Brook, New York 11794

David Z. Piper
Pacific-Arctic Branch of Marine Geology, US Geological Survey, Menlo Park, California 94025

A thick ferromanganese deposit encrusting fresh basaltic glass has been dredged from the Hess Deep in the eastern Pacific. Contiguous layers within the Fe–Mn crust have been analysed for uranium-series isotopes and metal contents. The rate of accumulation of the deposit, based on the decline of uranium-unsupported ^{230}Th, is calculated to be approximately 50 mm per 10^6 yr. Based on hydration-rind dating of the underlying glass and an 'exposure age' calculation, this rate is concluded to be too slow, and an accretion rate on the order of 1 mm per 10^3 yr is more consistent with our data.

INDURATED metal-rich crusts associated with probable hydrothermal areas on the seafloor have been reported[1–4]. Ferromanganese encrustations, sampled on active spreading centres, include those from the Mid-Atlantic Ridge, sampled during the Trans-Atlantic Geotraverse (TAG) expedition[2,3] and during the FAMOUS project[4], from the flank of a seamount at the crest of the East Pacific Rise[1], and from the Galapagos Spreading Center[5]. These deposits have been attributed to precipitation from hydrothermal fluids which gained high metal contents during interaction of seawater with basaltic rock at elevated temperatures. Although not conclusive, this type of genesis is more consistent with the geochemical and geological evidence than is a diagenetic formation by metal remobilisation and subsequent precipitation within sediment or formation by direct precipitation from seawater. Experimental evidence[7,8] showing that seawater becomes greatly enriched in Fe and Mn during interaction with fresh basalt at elevated temperatures seems to support the hydrothermal origin.

Table 1 Chemical composition of crust from station 1052 compared with other reported hydrothermal deposits and an average Pacific manganese nodule

Sample	Location	Fe	Mn	Ni	Co	Cu	Zn	Fe/Mn
		(% by weight)			(p.p.m.)			
1052 (0–3 mm)	Hess Deep	21.8	16.7	1,950	508	735	543	1.30
D6 (0–3 mm) (data from ref. 6)	Galapagos Spreading Center	0.016	52.7	100	< 23	43	105	0.0003
T3-72D 253-13-21 (0–5 mm) (from ref. 2)	Mid-Atlantic Ridge (~26 °N)	0.011	39.2	100	18	12	—	0.0003
AMPH D2 (from ref. 3)	Flank of East Pacific Rise	32.5	1.94	400	35	74	—	16.7
Average nodule	Pacific	14.3	19.7	7,220	3,810	3,660	—	0.72

These ferromanganese deposits are characterised by low Th contents, high apparent rates of accumulation, and immediate proximity to sources of submarine volcanism. Samples from the TAG area[2,5] and the Galapagos Spreading Center[6] are further characterised by extremely low Fe and high Mn contents. Conversely, other suggested hydrothermal deposits are extremely Fe-rich and very low in Mn. The AMPH D2 deposit from a seamount on the flank of the East Pacific Rise, for example, has a Fe/Mn ratio of 16.7 (ref. 3). Unconsolidated metalliferous sediment such as that found along the crest of the East Pacific Rise generally have Fe/Mn ratios close to 3.0. Bonatti[9] suggests that the wide range of Fe/Mn ratios in these hydrothermal deposits is probably caused by drastic fractionation of the two elements, both before and after discharge of the metal-bearing solutions on to the sea floor. We report here on the geochemistry of a ferromanganese crust which is compositionally intermediate between the Mn-rich[2,5,6] and Fe-rich hydrothermal deposits[3,9]. We present evidence to demonstrate that this deposit must have formed at a substantially higher rate than deep-sea manganese nodules which are similar in their Fe/Mn ratios.

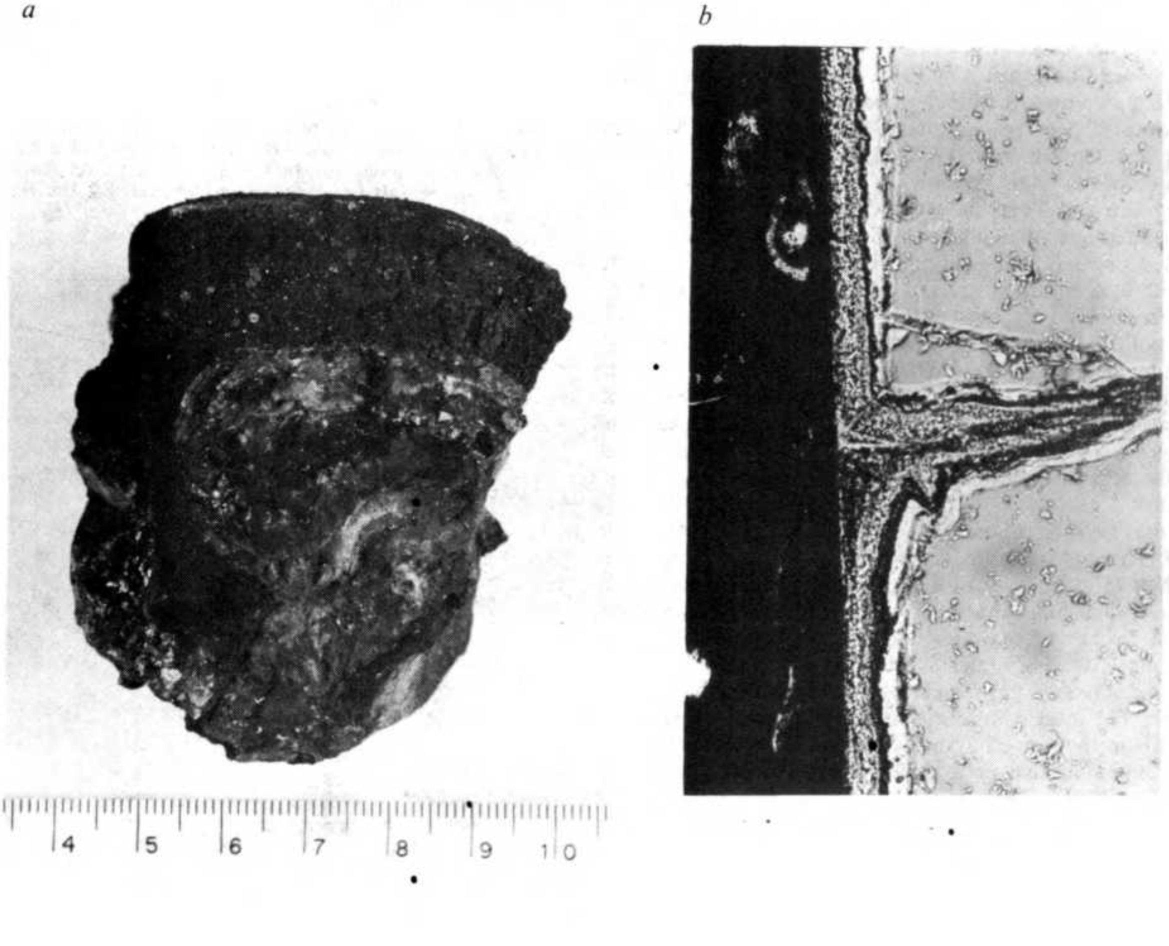
Our sample was collected at station 1052, on cruise 14 of the USSR RV Dmitry Mendeleev, at a depth of 3150 m, at 2° 17.8′N and 101° 1.5′W. The station is located in the axis of the Galapagos Spreading Center, just east of its junction with the East Pacific Rise. This area is known as Hess Deep[10] because of its relatively great depth for an oceanic rise system.

Chemical composition

The sample which we analysed consisted of 16 mm of ferromanganese material encrusting fresh basaltic glass (Fig. 1). Table 1 shows the chemical composition of the crust from station 1052 as compared to other reported hydrothermal deposits and to an 'average' Pacific manganese nodule. Analyses were performed by instrumental neutron activation analysis except for Cu and Ni which were determined by atomic absorption. Microprobe analyses of the underlying glass reveal typical ocean theolitic composition with low alkalis and a SiO_2 content of about 50%.

This sample is unlike the Mn-rich deposits from the TAG area and the Galapagos Spreading Center, having a much higher Fe and trace metal content. It is not as Fe-rich, however, as the iron deposit AMPH D2 from the flank of the East Pacific

Fig. 1 Photograph and microphotograph of thin section cut from sample 1052. Scale in (*a*) is in cm; the width of (*b*) is equivalent to approximately 1 mm.



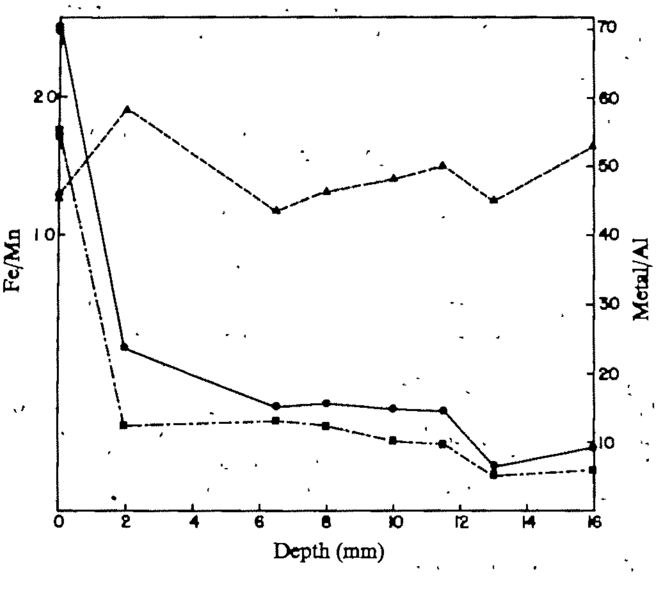


Fig. 2 Fe/Mn (▲), Fe/Al (●) and Mn/Al (■) ratios as a function of depth in ferromanganese crust as determined by microprobe analyses.

Rise. The minor metals reported in Table 1 for our Fe–Mn crust are all within the reported ranges for these metals in manganese nodules. The concentrations of Ni, Co and Cu, however, are near the minimum values found in nodules and cannot be described as typical. The only mineral detected in the crustal portion of our sample by X-ray diffraction procedures was δ-MnO_2.

Scott *et al.*[3] suggested that the extreme fractionation of Mn from Fe in deposits from the TAG area may result from the different solubilities of oxides of iron compared with Mn during oxidation by dissolved oxygen[11]. The reasoning is that Mn tends to be transported further from the source whereas Fe is precipitated at lower levels as oxides or sulphides. If this type of situation is representative of metal transfer in hydrothermal areas of the sea floor, then we may have, by chance, sampled an intermediate zone where both Fe and Mn are being deposited simultaneously. Scott *et al.*[5] have shown that the Mn-rich hydrothermal deposits from the TAG area are later covered by a more Fe-rich material, possibly of hydrogenous (seawater) origin. Moore and Vogt[4] have shown the same relation for a sample located near the Galapagos Spreading Center.

Figure 2 presents compositional data obtained at different levels within a polished section of 1052 using an electron microprobe. The Fe/Mn ratio remains between 1 and 2 throughout, but both the Fe/Al and Mn/Al ratios have a steep gradient in the outer portion of the crust. These metal/Al ratios reach levels on the exterior similar to those reported for EPR crest metalliferous sediments[12]. The reason for these steep gradients is not clear, although the concentration of volcanic debris (especially laths of plagioclase) was higher toward the interior of the crust.

Like the Fe/Mn ratios, the concentration of rare earth elements (REE) is uniform. The Ce/Fe and Eu/Fe ratios vary by less than 25% for seven of the layers analysed. The curve for the average REE concentrations, normalised to shale, is similar in pattern to that of seawater and crestal sediment from the East Pacific Rise (Fig. 3). This pattern is characterised by a negative Ce anomaly and enrichment of heavy REE relative to light REE. The total concentration of REE, however, is quite high and is in the range of concentrations for ferromanganese nodules, representative of a slowly accumulating manganese deposit. The shape of the curve, however, differs markedly from that of nodules. The curve for Pacific Ocean nodules which give similar X-ray diffraction patterns, usually have a positive Ce anomaly and slight depletion of the heavy (REE) Yb and Lu.

Growth rates

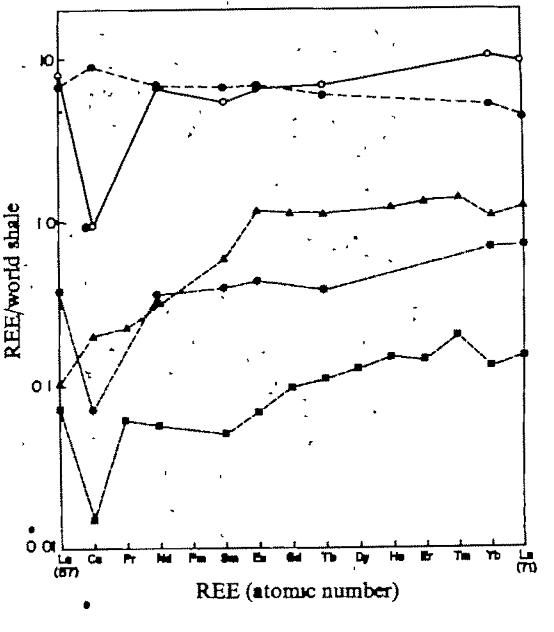
To assess the rate of growth of this deposit, uranium-series isotopes were measured in six contiguous layers throughout the crust. Separation, purification and counting of U and Th isotopes involved standard techniques[13]. The individual sections of the crust were removed by scraping the material from a measured area, weighing the material recovered, and calculating the depth based on an assumed density of 1.96 g cm^{-3} (ref. 14). Because of the configuration of this particular sample (Fig. 1), it was possible to measure directly the thickness of each interval by measuring the remaining thickness after each section was scraped away. The agreement between those two estimates was quite good, and it is estimated that the accuracy of the depth intervals is better than ±10%.

When the uranium-unsupported ^{230}Th activity is plotted relative to depth within the crust, a steep exponential curve results (Fig. 4*a*). If a constant rate of deposition of the ferromanganese material and a constant flux of ^{230}Th are assumed, and if the decline of the excess ^{230}Th is due solely to radioactive decay, we can estimate the rate of accretion of this material by dividing the depth interval over which half the activity of ^{230}Th disappears by the half life of ^{230}Th (75,200 yr). The resulting rate, 47.9 mm per 10^6 yr, is about one order of magnitude higher than typical rates deduced for deep-sea manganese nodules[15]. Although this rate is relatively high, there are several lines of evidence which indicate that, in fact, it must have grown considerably faster.

The assumption that the ^{230}Th gradient is due solely to radioactive decay is suspect because of the strong ^{232}Th gradient measured in the outer 8 mm of the crust (Fig. 4*a*). The slope of the ^{232}Th activity in this portion of the crust is so similar to that of ^{230}Th that when the excess ^{230}Th is normalised to ^{232}Th, there is virtually no slope (Fig. 4*b*). The deposit would have had to accrete at a minimum rate of about 100 mm per 10^6 yr to obscure a gradient in the $^{230}Th/^{232}Th$ ratio.

Another inconsistency in the uranium-series data concerns the isotopic composition of uranium throughout the thickness of the crust. The $^{234}U/^{238}U$ activity ratio for five of the six intervals analysed (Fig. 4*b*) is within analytical error of that in modern-day ocean water[16]. If this crust had accreted at an

Fig. 3 Rare earth elements (REE) in crustal portion of 1052 (○) and other marine phases normalised to shale. The curve for 'ferromanganese nodule' (●) is an analysis[13] of a nodule with similar mineralogy (δ-MnO_2) as the crust from station 1052. The ridge basalt (▲) analysis is from ref. 24, the East Pacific Rise (★) sediment from ref. 25, and seawater (■; data × 10^6) from ref. 26.



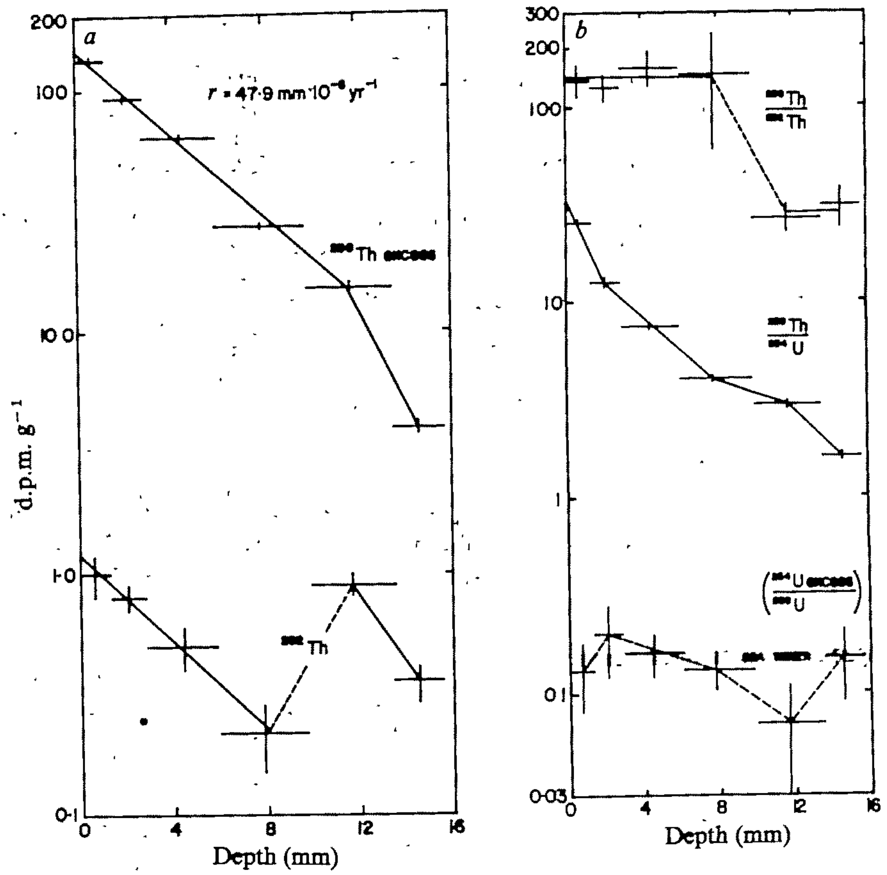


Fig. 4 *a*, Uranium-unsupported ^{230}Th activity and activity of ^{232}Th plotted against depth in ferromanganese layers of 1052. *b*, Activity ratios of ^{230}Th/^{232}Th, ^{230}Th/^{234}U and ^{234}U excess/^{238}U as a function of depth of ferromanganese in sample 1052. Horizontal error bars indicate range in thickness of layer sampled. Vertical error bars indicate 1σ errors as calculated from counting statistics.

average rate of 47.9 mm per 10^6 yr, the age of the base of the crust would be approximately 320,000 yr. If the uranium in the deposit had been derived from seawater and remained a closed system throughout its history, we would expect a ^{234}U/^{238}U activity ratio of about 1.06 for the basal layer of the crust. This is clearly not the case, and requires that we either had open exchange of uranium between the ferromanganese and seawater or the deposit is quite youthful.

Although it is difficult to reconcile the radiochemical data in terms of a slow rate of growth, we cannot conclusively demonstrate that the deposit formed at a faster or slower rate than calculated here, without an independent assessment of the age of the deposit. Because a well-developed zone of palagonite was present between the fresh basaltic glass and the ferromanganese, we tried to date the glass by hydration-rind techniques. This method, known to archaeologists as 'obsidian dating'[17], has also been applied to geological problems[18]. Because of the relative compositional uniformity of submarine basaltic glasses and the very constant ambient temperatures of oceanic bottom waters, the dating of submarine glasses by this technique seems to be reliable[19,20]. The principal assumption of the hydration-rind method is that the rate of submarine palagonisation of basaltic glass is constant, making it possible to obtain an age of the glass by simply measuring the extent of the hydration. An average rate of submarine palagonisation of 2.91 μm per 10^3 yr was obtained[20] by measuring the thickness of the hydration rind in submarine samples of known age. This rate has recently been confirmed on samples from the Mid-Atlantic Ridge, in which age was assessed by fission-track dating[21].

Using a thin section cut normal to the plane of growth of the ferromanganese material, several dozen traverses were made across the hydration rind using a microscope with a calibrated micrometer. This rind can be seen in the photomicrograph (Fig. 1*b*). The average thickness of the palagonite was 56±4 μm. This corresponds to a hydration age of 19,000±1,500 yr, much lower than the calculated minimum age of 320,000 yr, for the volcanic glass found by extrapolating the excess ^{230}Th data to the base of the crust.

Another way of estimating the age of this deposit from radiochemical data is to calculate an excess ^{230}Th 'exposure age'[14]. Assuming that the deposit contained no initial excess ^{230}Th but acquired its present-day content by exposure to normal ocean water, we can calculate the duration of this exposure by simply dividing the integrated content of excess ^{230}Th by its flux to the sea floor. The ferromanganese crust contains 145 d.p.m. ^{230}Th$_{ex}$ cm^{-2} and the flux of ^{230}Th is calculated to be 2.35 d.p.m. cm^{-2} per 10^3 yr per km of seawater on the basis of the normal uranium content of seawater with a 15% excess of ^{234}U and assuming quantitative removal of ^{230}Th produced from uranium. The 'exposure age' resulting from this calculating is 18,500 yr, in excellent agreement with the 'hydration age' of 19,000 yr.

Although our exposure age calculation produces an 'age' in apparent agreement with our hydration date, the cause of the exponential gradients of the Th isotopes must still be explained. It seems unlikely that ^{230}Th could diffuse over 15 mm in only 19,000 yr. Scott *et al.*[8] discussed the apparent inverse relationship between rates of manganese crust accumulation and content of trace metals. If the amount of thorium incorporated into a ferromanganese crust is also inversely proportional to its growth rate, then the gradients that we have measured could simply be a result of the accretion rate slowing down.

Our age estimates for this deposit (1052) are summarised below.

(1) Extrapolation of rate derived from excess ^{230}Th gradient:

Apparent rate of growth	= 47.9 mm per 10^6 yr
Thickness of crust	= 15.5 mm
Minimum age of glass	= 320,000 yr

(2) Hydration-rind dating of basaltic glass:

Rate of submarine palagonitisation	= 2.91 μm per 10^3 yr
Average thickness of palagonite rind	= 56 μm
'Hydration' age of glass	= 19,000±1,500 yr

(3) Time required to acquire integrated amount of excess ^{230}Th

$$\sum {}^{230}\mathrm{Th}_{ex} = \int_{0}^{\infty} {}^{230}\mathrm{Th}_{0}\rho \exp(-\lambda^{D})\mathrm{d}D$$

where $^{230}\mathrm{Th}_0$ = extrapolated surface activity of excess ^{230}Th (d.p.m. g^{-1}); ρ = bulk density (g cm^{-3}); D = depth in crust; $\lambda = 0.693/D^{\frac{1}{2}}$ ($D^{\frac{1}{2}}$ = depth at which activity of excess ^{230}Th equals $\frac{1}{2}$ that of surface value) and ^{230}Th flux = 2.35 d.p.m. cm^{-2} per 10^3 yr per km seawater. Depth of crust = 3,340 m.

For 1,052: $\Sigma^{230}\mathrm{Th}_{ex}$ = 145 d.p.m. cm^{-2}. Therefore, 'exposure' age = 18,500 yr.

Based on the correspondence between the ages derived from hydration-rind and ^{230}Th flux techniques, and the fact that the ^{230}Th distribution in the ferromanganese crust precludes radioactive decay being the only process affecting the ^{230}Th gradient, the lower age estimate for this sample would seem to be the more accurate estimate. If the age of the volcanic glass is actually about 19,000 yr, the minimum rate of accretion of the Fe–Mn oxides would be about 800 mm per 10^6 yr. In fact, it must have been even faster, since we have calculated that more than 18,000 yr of exposure to seawater would be necessary for accumulation of the excess ^{230}Th that is present in the crust today. Volcanism could have supplied some of the ionium, but this is unlikely since other hydrothermal deposits sampled from oceanic ridges have been shown to contain no excess ^{230}Th (refs 2 and 6).

Conclusions

Our results show that in our sample from the Hess Deep, first, a ferromanganese crust has been deposited without severe fractionation between Fe and Mn. Second, the trace metals Ni, Co and Cu are low compared with typical manganese nodules but the content of REE is about the same. Third, the REE pattern, normalised to shale, is very similar to the seawater pattern. Fourth, the major assumptions in applying U-series dating techniques for assessing rates of growth seem to fail in this case and we conclude that the deposit must have accreted considerably faster than that indicated by the excess ^{230}Th method.

On the basis of these results, we suggest that Fe and Mn as well as some of the trace metals in this crust were deposited from hydrothermal fluids while REE were scavenged from seawater.

This study was supported by the NSF–IDOE Nazca Plate Program through a grant to the University of Hawaii. We were visiting scientists on board the USSR Research Ship Dmitry Mendeleev during her 14th cruise in the eastern Pacific; we thank our Soviet colleagues for cooperation. We thank Oliver Schaeffer, Bill Moore and Yousif Kharaka for comments on the original manuscript, and Floyd Hodges and Maury Morgenstein for technical assistance.

Electrophoresis along cell membranes

Lionel F. Jaffe

Biology Department, Purdue University, Lafayette, Indiana 47907

Bioelectric fields may segregate charged components floating in the plasma membranes of cells by a process of electrophoresis along the membrane. Molecules in cell membranes may be sorted to different portions of the cell surface by such electrical gradients. We present here a theory to support this hypothesis.

MANY molecules and particles are freer to move along the outer membrane of cells than out of this membrane[1,2]. Many of the externally protruding components bear a high negative charge density[3–6]; whereas lecithin (and sphingomyelin) have a substantial positive charge at the calcium ion concentrations typical of extracellular fluids[7,8], and neutral lipids such as cholesterol and certain glycolipids are also common in the outer leaflets of cell membranes[9,10]. If lateral mobility and charge heterogeneity among these membrane components are sufficient, application of a steady field to a cell should substantially redistribute them within the plane of the plasma membrane (Fig. 1). This process may be called surface, lateral, or perhaps perimembrane electrophoresis. I present here a study of the basis and implications of this idea.

Equilibrium electrophoresis along the membrane of a spherical cell

A complete theory of lateral electrophoresis is analogous to the theory of sedimentation. Both the equilibrium with back diffusion and the approach to this equilibrium must be considered. For the present purpose, only the simpler and apparently more useful equilibrium theory will be presented.

Consider a spherical cell which bears a population of one species of negatively charged molecules or particles on its surface, and which is placed in a uniform field (Fig. 1). Neglect any interactions (other than hydrodynamic drag) between various surface components. Allow them to come to equilibrium between electrophoresis which tends to concentrate them at the positive pole and back diffusion. It will be shown that the equilibrium surface concentration, C, is given by

$$C = \overline{C}[\varepsilon \cdot \mathrm{csch}(\varepsilon)]e^{\varepsilon \cos \theta}, \qquad (1)$$

where $\overline{C}$ = the particles' average concentration, $\varepsilon = (m/D) \cdot (\overline{V}/2)$, m = electrophoretic mobility, D = diffusion constant,

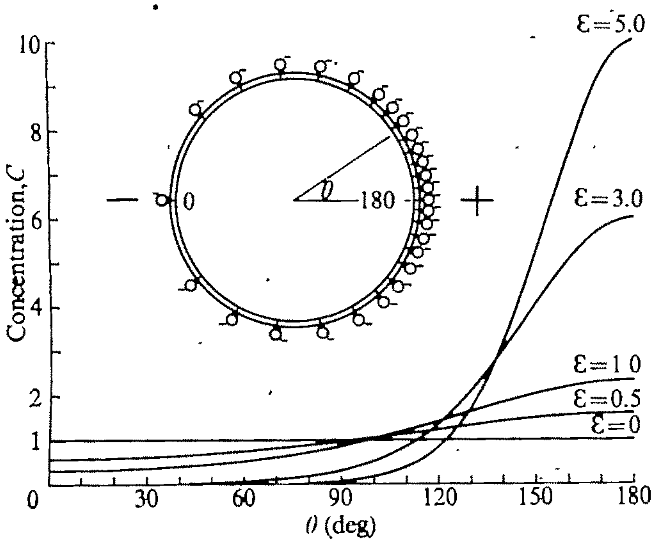

Fig. 1 Distributions of mobile charged particles on the surface of a sphere at electrophoretic equilibrium. Curves plot equation (1).

and $\bar{V}$ = voltage difference established across the sphere by the field. This is plotted in Fig. 1.

The particles are at a true equilibrium between several forces produced by the external field and Brownian movement, so it might be supposed that a Boltzmann distribution could be applied. Their counter ions are not, however, in equilibrium but in a steady state, so this most direct method cannot be used. Instead one writes the equation for a balance between electrophoretic and diffusional transport

$$mC(\mathrm{d}V/\mathrm{d}S) = D(\mathrm{d}C/\mathrm{d}S) \tag{2}$$

A sphere is known to distort an otherwise uniform field so that the potential just outside its surface, V, remains proportional to cosθ (ref. 11). Hence

$$V = (\bar{V}/2)\cos\theta \tag{3}$$

Substituting equation (3) in (2) and integrating yields equation (1).

Exactly the same derivation holds for the distribution of particles attached to the inner surface of a cell's membrane and concentrated by a uniform internal field, except that in this internal case $\bar{V}$ would refer to the transcytoplasmic potential difference. A uniform internal field might be set up by either a uniform external one[11] or by a cosine varying current source in the cell's own plasma membrane[12].

For comparison with cells' galvanotropic responses (or perhaps other polar responses) it is helpful to characterise the degree of polarisation of each of these equilibrium distributions[1] by some parameter, φ. The tropistic responses of cell populations are commonly characterised by the weighted cosine of the distribution of outgrowth angles (13)

$$V_1 = \Sigma n \cos\theta / \Sigma n \tag{4}$$

where n is the number of outgrowths at an angle, θ.

Hence we define φ in an analogous way

$$\varphi = \int C \cos\theta \, \mathrm{d}s / \int C \, \mathrm{d}S \tag{5}$$

Note that if the outgrowth angles or surface particles were all concentrated at one pole or the other, V_1 and φ would be +1 or −1 whereas if they were evenly distributed, these parameters would have a value of zero.

Integration of equation (5) yields

$$\varphi = \mathit{ctnh}\,(\varepsilon) - \varepsilon^{-1} \tag{6}$$

Use of Pierce's series[14] number 793 yields

$$\varphi = \varepsilon/3 - 0.133\,\varepsilon^3 + 0.127\,\varepsilon^5 \ldots . \tag{6a}$$

This suggests that for $\varepsilon < 1$, φ is usefully approximated by

$$\varphi \simeq \varepsilon/3 = (m/D)(\bar{V}/6). \tag{6b}$$

Equations (6) and (6b) are plotted in Fig. 2.

Expected polarisability of real membrane particle distributions

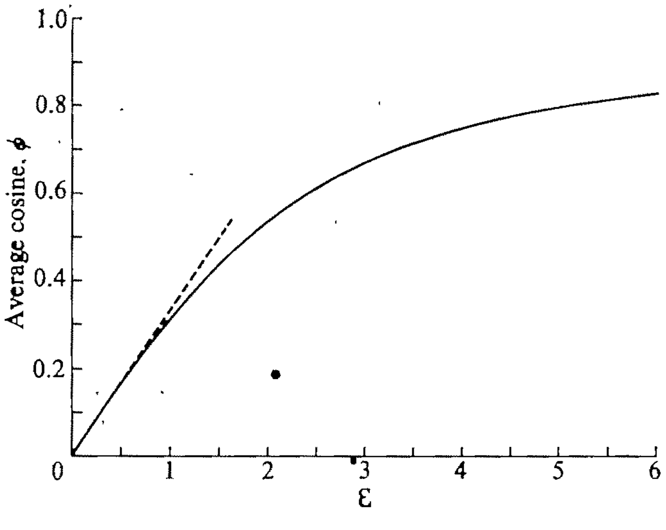
Let us characterise the polarisability of a particle distribution on a cell by the voltage $\bar{V}_{0.1}$ required to induce a polarisation of 0.1. From equation (6b) one gets

$$V_{0.1} = 0.6\,(D/m) \tag{6c}$$

To estimate this voltage, one must estimate the diffusion to mobility ratio, D/m of the particles being redistributed. We will show below that the larger and more highly charged particles found in cell membranes are likely to have D/m values of about a millivolt. So we predict that long-lasting fields, whether endogenous or imposed, are likely to bring about significant electrophoresis along cell membranes when the voltage drop per cell is only one to a few millivolts.

To estimate D/m values, we will first show that D/m is independent of the drag, f, which they encounter. This drag is an estimated 100–1,000 times greater than such particles would meet if they were only hindered by the extracellular medium[8]. If this greater drag were exerted by the viscosity of the medium which fills and surrounds their electrical double layer, then D and m are both well known to vary with f^{-1}. Hence D/m would be independent of f. It is likely, however, that this extra drag is exerted on a sort of molecular clog, that is, a part or extension of each particle that lies within the lipid bilayer and is not surrounded by a field-sensitive double layer; whereas the electrical pull is exerted on each particle's 'sail', that is, its part that extends outside of the bilayer in the external aqueous phase (Fig. 1). Then m would equal F, the net electrophoretic force per field (which acts on the sail), divided by the drag which acts on the clog. Henry's analysis[15], directly confirmed by Sumner and Henry's experiment[16], shows F to be unchanged whether the particle is free or tethered. Hence m is inversely proportional to the drag wherever it originates. Since this also holds for D (ref. 17), D/m is again independent of the drag.

Fig. 2 Average cosines of the distributions shown in Fig. 1. The curve plots equation (6); the dashed line, equation (6b).



Since D/m values are independent of the drag, we can use the values known for molecules or particles immersed in the usual 1-cP aqueous media. In media with this viscosity (and an ionic strength of 0.05 M) most biological molecules or particles have electrophoretic mobilities in the range from 1 to 3, or occasionally up to 5×10^{-4} cm s^{-1} (V cm^{-1})$^{-1}$ (refs 5, 18). Electrophoretic mobilities are independent of the component's radius, but diffusion constants are inversely proportional to it. So to estimate how small a voltage drop per cell may be expected to bring about significant redistribution, let us consider relatively large membrane particles. Let us consider spherical particles with 10-nm diameters since the larger particles seen in freeze-fracture electron micrographs of plasma membranes are of about that size and shape[19–22]. In 1-cP media, such 10-nm spheres have a diffusion constant of 4×10^{-7} cm^2 s^{-1} (ref. 24). Then considering particles with a mobility value of 3×10^{-4} units, which is towards the upper end of those usually found, one obtains a D/m value of 1.3 mV and applying equation (6) we infer that the distribution of such particles would be one tenth to one half polarised by a steady voltage drop of only 0.8–4.0 mV.

Application of this equilibrium theory is restricted to the action of sufficiently long-lasting fields. The time needed is of the order of L^2/D where L is the cell's pertinent diameter and D the segregated components diffusion constant. The larger mobile components of cell membranes tend to have diffusion constants in the vicinity of 10^{-9} cm^2 s^{-1} (ref. 2), so for a 30-μm (that is, 3×10^{-3}-cm) cell, the equilibrium approach time might be about 10^4 s, or 3 h. When one considers that the bioelectric fields associated with growth and development generally last for hours to days or even weeks (that is, 10^4 to 10^6 s), one concludes that an equilibrium theory may be widely relevant.

The accompanying paper, by Poo and Robinson[25] seems to directly demonstrate the predicted phenomenon of lateral electrophoresis along the surface of explanted, embryonic muscle cells exposed to an artificially imposed field. Moreover, a number of galvanotropic responses of isolated plant cells to artificial fields occur in response to such small voltage drops as to suggest mediation by lateral electrophoresis[26–28].

Natural fields along cell membranes

Perhaps the most obvious place where large endogenous voltage drops occur along cell membranes is along the outside of the lateral membranes of cells in various metazoan epithelia. Various mature epithelia are well known to maintain voltage drops of 30–100 mV or more across themselves[29]. Furthermore, there are several reports of 3–10 mV potential drops across embryonic cell layers, for example, the mammalian blastocyst wall[30], a fish gastrula wall[31], and the chick chorioallantoic membrane[32]. A second place where good evidence for significant steady potentials drops along cell membranes can be cited is along the outer plasma membranes of epidermal cells in the coleoptiles of oat seedlings. A voltage drop of at least 40 mV (refs 33, 34) is measured along the axis of these organs and hence across about 30 cells in series[35]; whereas up to 80 or 90 mV appears across the axis in response to a gravitational stimulus[36,37] and thus across about 100 surface cells in series[35]. Thus, in both directions, about 1 mV per cell is present.

There are, moreover, at least three instances in which there is evidence that cells generate large enough cytoplasmic fields within themselves electrophoretically to segregate components of the inner leaflet of the plasma membrane. Woodruff and Telfer have quite directly measured a voltage drop of about 10 mV across the cytoplasmic bridge joining a developing insect oocyte and its nurse cell[38]; Hagins has measured a steady dark current outside of rat visual rod cells and infers an internal current sufficient to maintain a steady difference of about 1.6 mV along the interior of the cell[39]; while Robinson and Jaffe have measured a calcium current through developing fucoid eggs which might maintain the order of a millivolt difference across the interior of the cell[40,41].

I conclude that endogenous voltage gradients sufficient to bring about electrophoresis along cell membranes are very widespread in living organisms.

Electrophoresis of concanavalin A receptors along embryonic muscle cell membrane

Mu-ming Poo* & Kenneth R. Robinson

Biology Department, Purdue University, West Lafayette, Indiana 47907

Fluorescent concanavalin A (con A)-labelling showed that an electric field of 4 V cm^{-1} grossly redistributed con A receptors along the plasma membranes of living muscle cells within 4 h. This field produced a voltage drop of 12 mV across these 30 μm-wide cells. The movement of receptors was independent of cell metabolism and seemed to be electrophoretic in nature.

STUDIES of the cell membrane have demonstrated the dynamic nature of membrane constituents[1–5]. Both proteins and lipids may undergo rotational and translational diffusion in the plane of the membrane[6]. In the accompanying paper[7], Jaffe demonstrates on theoretical grounds that small voltage

---

*Present address: Department of Physiology, California College of Medicine, University of California, Irvine, California 92717.

differences (of the order of 1 mV across a cell) applied parallel to the surface of cells should be effective in redistributing charged, mobile entities in the plane of the membrane. We have placed cultured embryonic amphibian muscle cells in a field of 4 V cm^{-1} and examined the subsequent distribution of the receptors of concanavalin A (con A). We found, using fluorescein isothiocynate (FITC) labelled con A, that these receptors become asymmetrically arranged within a few hours. The receptors (presumably glycoproteins) accumulated on the side of the cells nearer the negative pole in a way consistent with a passive electrophoretic mechanism.

Muscle cells were obtained from the neural tube region of 1-d-old *Xenopus laevis* embryos (stage 18–19 by the criterion of Nieuwkoop and Faber[8]). After removal of the vitelline membrane, the neural tube and the underlying mesoderm were cut from the embryo in Ca^{2+}-, Mg^{2+}-free Steinberg's solution containing 0.4 mM EDTA (ref. 9). When the cells became dissociated, they were transferred to a shallow, rectangular glass chamber which was precoated with poly-L-lysine. The cells were cultured in Steinberg's solution supplemented with 10% Leibovits medium (L15, GIBCO) and 5% foetal calf serum (GIBCO). The *p*H of the culture medium was 7.8. Each culture contained various cell types from a single embryo and was incubated at room temperature (about 25 °C). Although neurones and other cell types survive for a while, after 2 d the predominate cells in the culture were single, spindle-shaped, striated muscle cells. These cells responded to 0.01% carbachol (Sigma) by contracting from both ends into a sphere.

The 0.5-mm deep chamber was covered with a coverslip before application of the electric field, thus providing a defined geometry. The current was applied through a pair of 8-cm-long bridges filled with Steinberg's solution gelled with 2% agar. These agar bridges isolated the cultures from contamination by the Ag–AgCl electrodes, to which a regulated power supply was connected. The applied fields were calculated from the current (1.5 mA usually), the medium's conductivity (130 Ω cm), and the chamber's cross section (0.05 cm^2). The usual current of 1.5 mA produced a field of 4 V cm^{-1} in the chamber.

After the field was shut off, the cells were cooled to 0–5 °C, the culture medium was washed off with Steinberg's solution, and then Steinberg's solution containing 200 μg ml^{-1} FITC–con A (Miles) was introduced into the chamber. After 10 min, the FITC–con A was removed with Steinberg's solution. In some cases the cells were then fixed in cold acetone (−5 to 0 °C) and preserved in 90% glycerol; in other cases, the living cells were examined by conventional and fluorescent microscopy. We found that glutaraldehyde fixation caused marked autofluorescence in these muscle cells, and glutaraldehyde thus was an unsuitable fixative.

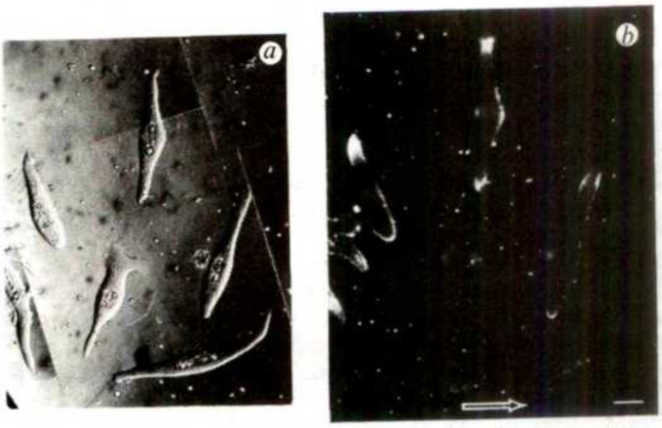

Fig. 1 FITC– con A-labelled living muscle cells observed by *a*, light miscroscope fitted with Normarski optics and *b*, dark-field fluorescence miscroscope. Embryonic muscle cells in monolayer culture exposed to a uniform electric field (4 V cm^{-1}) for 4.5 h before staining. Fluorescent 'ring' showed asymmetry for nearly all cells in the culture, with more stain accumulated towards the negative pole of the field (to the right of the figure). The brighter stain near the tips of some cells was due to partial contraction of the cells which we assume caused folding of the membrane resulting in higher concentration of con A receptors. Fluorescent spots in the background and on the surface of some cells were due to stained cell debris. Direct visual comparison of the fluorescence intensity on two sides of the cells were carried out for all cells which were aligned relatively perpendicular to the direction of the field. Labelling was done at 0–5 °C for 10 min. Bar: 30 μm.

Table 1 Con A receptor distribution in electrical field

Duration of electric field application* (and voltage drop across each cell)	No. of cells examined†	No. of cells showing asymmetry in the fluorescence 'ring' staining					Description of the asymmetry in fluorescence
		Towards (−) pole		Towards (+) pole		Indeterminant	
0	53	7	(13%)	10	(19%)	36	no detectable asymmetry
30 min (12 mV)	77	18	(23%)	16	(21%)	43	no detectable asymmetry
1.5 h (12 mV)	103	67	(65%)	11	(11%)	25	weak but definite asymmetry
4.5 h (12 mV)	86	70	(81%)	3	(3%)	13	striking asymmetry
14 h (12 mV)	27	25	(92%)	0	(0%)	2	striking asymmetry
24 h (0.6 mV)	60	27	(45%)	9	(15%)	24	weak but definite asymmetry

*All data for 12 mV voltage drop are from the same experiment; data for 0.6 mV voltage drop are from two other experiments.

†Cells were randomly sampled with only one criterion: their long axes were aligned within 30 degrees with respect to the direction normal to the field direction, so that the fluorescence staining on two sides of the cell could be compared (see text for detail).

The fluorescent microscopy was done using a standard Zeiss microscope fitted with a dark-field condenser. The excitation source was a Zeiss HBO 200W/4 lamp. Exciting light was passed through a heat-absorbing filter and a BG 12 blue filter, and emitted light was filtered with a No. 50 barrier filter.

Redistribution of con A receptors

In control cultures, where no electric field was applied, the FITC–con A-labelled cells showed uniform staining with a bright ring around the cell periphery since the surface is seen edge-on there (Fig. 2*a*). This ring was our most reliable and sensitive indicator of receptor redistribution. The labelling was specific, since it was completely blocked by 0.1 M α-methyl-D-mannoside, one of the sugars for which con A is specific[10]. Further, most of the label on prelabelled cells was removed by applying 0.1 M α-methyl-D-mannoside for 10 min.

When an electric field of 4 V cm^{-1} was applied to cell cultures for 4.5 h, nearly all cells whose long axis was perpendicular to the field showed a striking asymmetry in their ring staining pattern, with more label appearing on the side of the cells facing the negative electrode (Fig. 1*b*). Bright-field microscopic observations (both phase-contrast and Nomarski) were made on the same cells and no morphological difference corresponding to the observed asymmetry in fluorescence staining could be seen (Fig. 1*a*). Cells that were oriented with their long axes parallel to the field also showed some accumulation of label at the negative-facing tip, but this effect was much smaller and harder to score than the asymmetry along the short axis.

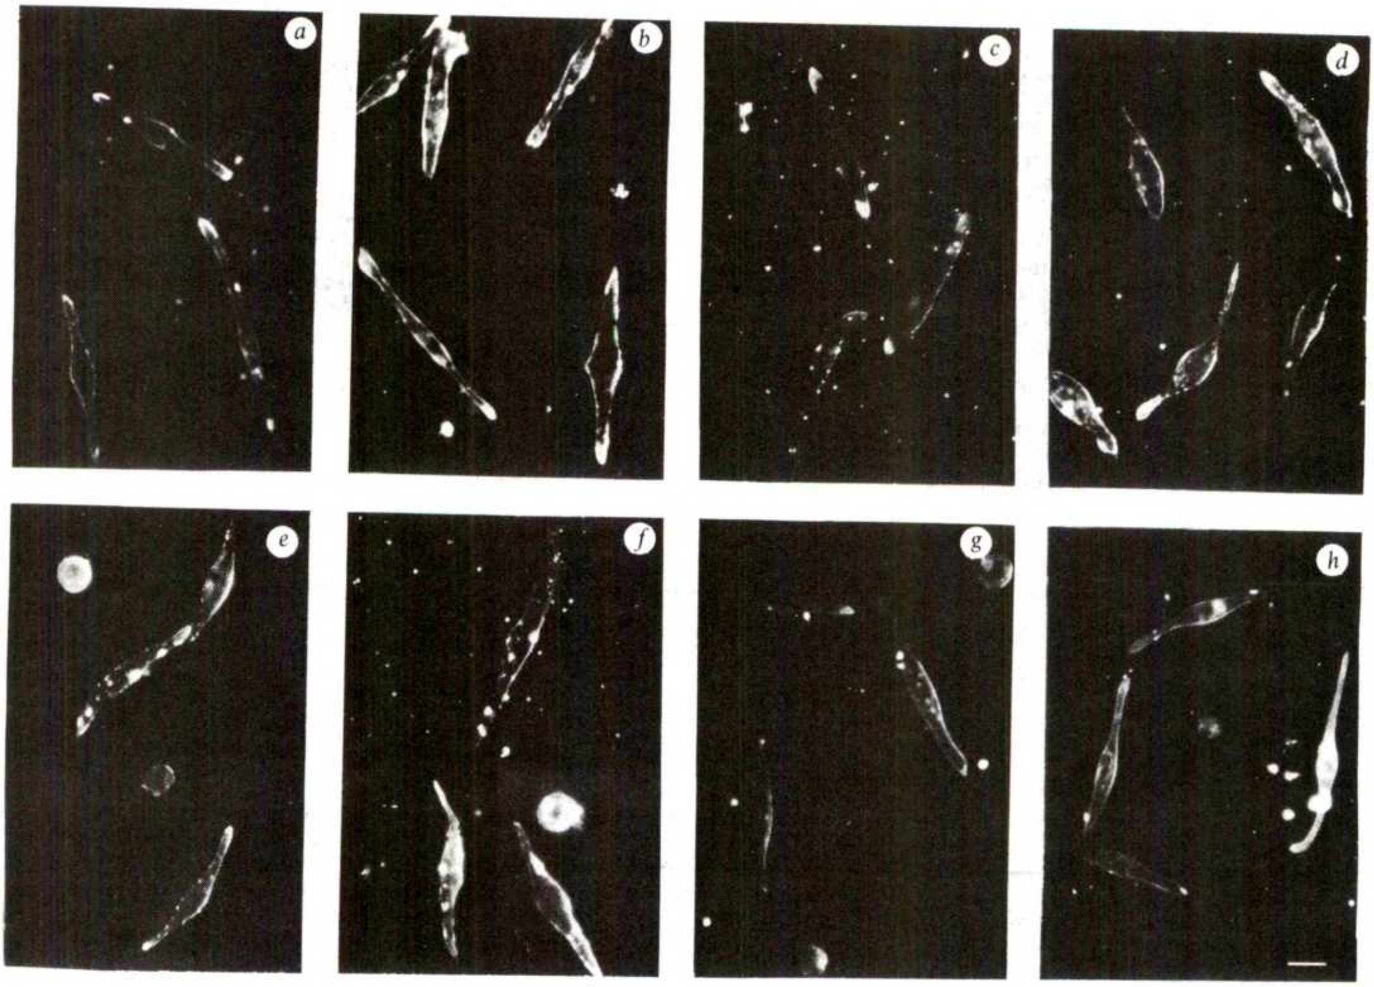

Fig. 2*a*, Control culture, where no field has been applied, FITC–con A-labelled cells showed uniform staining with a bright ring around the cell periphery. *b*, *c*, *d*, Cells were exposed to an electric field of 4 V cm^{-1} for 30 min, 1.5 h, and 4.5 h, respectively, before FITC–con A labelling. *e*, Cells were preincubated in Steinberg's solution containing 10^{-2} M sodium azide and 10^{-3} M dinitrophenol for 2 h. A field of 4 V cm^{-1} was then applied for 2 h before labelling. Both field application and FITC–con A labelling were carried out in the presence of these compounds. *f*, Cells treated as in (*e*) except the Steinberg's solution contained 10^{-2} M sodium arsenate, 10^{-3} M sodium fluoride, and 10^{-3} M dinitrophenol. *g*, Cells treated as those in (*d*) except Ca^{2+} was omitted from the medium during the application of the field. *h*, Cells treated as those in (*d*) except FITC-conjugated wheat germ agglutinin was used as a fluorescent label instead of FITC–con A. All cells were fixed with cold acetone (at 0 to +5 °C) after labelling. Negative pole of the field was on the right of the figure. Bar: 30 μm.

To investigate the time course of the redistribution, we applied the same field (4 V cm^{-1}) to a group of cultures for 30 min, 1.5 h, 4.5 h, and 14 h. The asymmetry in fluorescence staining on cells which had their long axes approximately perpendicular to the field was then scored (see Fig. 2*a*–*d*). We found that the effect was clearly perceivable after 1.5 h in the field and that it did not seem to increase beyond 4.5 h. Table 1 shows data from one experiment; similar results were obtained in four separate experiments. We concluded that the con A receptor moves halfway across the surface of the 30-μm-wide muscle cell in 1–2 h.

After a field as small as 0.2 V cm^{-1} (corresponding to a potential difference of 0.6 mV across a 30-μm cell) was applied to a culture for 24 h, a detectable asymmetry in the con A receptors was found (see Table 1). Fields smaller than 0.2 mV cm^{-1} did not cause detectable redistribution.

We have considered the possibility that the apparent positive charge of the con A receptors was due to the polycation, poly-L-lysine, that was used to coat the surface of the glass on which the cells were grown. The cells grew well on clean, untreated glass, so the experiment was repeated in the absence of poly-L-lysine, with a field of 4 V cm^{-1}. The same obvious accumulation of the con A receptors on the negative side of the cell was seen after 4 h.

In two separate experiments, FITC-wheat germ agglutinin (WGA) was added to cells which were in a 4 V cm^{-1} field for 4.5 h. Some cells seemed to show a slight accumulation towards the negative side (Fig. 2*h*); however, a count of cells such as was done for Table 1 showed that the asymmetry was less than was seen for the con A receptors after 1 h in the field. The WGA receptor is thus either much less charged or much less mobile than the con A receptor.

Mechanism of receptor redistribution

We considered the redistribution of the con A receptors in an electric field to be a passive, electrophoretic phenomenon. As an alternative, however, the field might somehow align and activate a motive system in the cortex of the cell which then actively redistributes surface components, including the con A receptors. Since any such system would presumably require metabolic energy, we performed experiments in the presence of metabolic inhibitors. First, we preincubated the cells in Steinberg's solution containing both 10^{-2} M sodium azide and 10^{-3} M dinitrophenol, a treatment known to prevent con A-induced capping in other cells[11,12]. As a second, more drastic test, we preincubated other cells in a medium including 10^{-2} M sodium arsenate, 10^{-3} M sodium fluoride, and 10^{-3} M dinitrophenol for 45 min. This latter treatment blocked their response to 0.01% carbachol, a carbachol concentration which caused instantaneous contraction in control cultures. This indicated that the cellular energy supply for the contractile machinery had been exhausted. Cells so pretreated were then placed in an electric field (still in the presence of the respective metabolic inhibitors) and the distribution of the con A receptors examined as before. Neither treatment had any effect: the con A receptors still accumulated on the negative side with the same time course and to the same extent as in control cells (see Fig. 2*e*, 2*f*). Similarly, the presence of 5×10^{-6} M colchicine throughout the experiment had no effect on the redistribution. Moreover, when Ca^{2+} was omitted from the medium ($[Ca^{2+}] < 10^{-5}$ M) during the application of the field, the redistribution proceeded as in the normal Ca^{2+} medium (Fig. 2*g*).

We therefore believe that the observed redistribution of the con A receptors is a passive response of these molecules to the electric field. As will be discussed later, the estimate of receptor mobility from these data is consistent with the idea of electrophoretic movement of receptor molecules through an environment with a drag similar to the measured drag on other cell membrane constituents[6]. Moreover, if the redistribution of the con A receptors is a passive electrophoretic movement, removal of the electric field after the receptor is asymmetrically distributed should allow a relaxation of the asymmetry due to back diffusion. Preliminary results indicated that if cells were allowed to remain in the culture medium following the application of a field but before the application of FITC-con A, there was a partial relaxation of the asymmetry. Some recovery to the original uniform distribution was apparent after 3 h. About 50% of the cells examined, however, still showed a weak asymmetry in the receptor distribution even after 54 h. Similar results were obtained in three separate experiments. The characteristic $1/e$ time for the partial relaxation of asymmetry is about 10 h (range 5–15 h). Relaxation experiments have not been performed in the conditions inhibiting metabolism, since the cells die if treated with drugs for the longer times required in these experiments.

Discussion

An externally applied electric field may exert its action on cultured muscle cells in several ways. It may act by producing a cytoplasmic potential gradient. It may act by changing the membrane potential on the two sides of the cell. It may also act tangentially along the surface of the cell. In our experiments, the potential difference produced by the field across a perpendicularly aligned muscle cell (average width 30 μm) was about 12 mV. Since only a very small fraction of the external voltage drop would lie across the cytoplasm, the directed movement of cytoplasmic components which could in turn redistribute surface receptors seems quite unlikely. The membrane potential on the two sides of the cell facing the electrodes will be shifted by about 6 mV. It is not clear, however, how this steady shift in membrane potential could have caused the observed redistribution of the receptor molecules in the plane of the membrane. Rather, we propose that the primary action of the applied field is to act tangentially along the membrane[7,13]. An external tangential field would be experienced by the charged, protruding heads of membrane-bound molecules, and these molecules would thus be driven (to the extent that they are mobile) towards the anodal or cathodal side of the cell. Quantitatively, this mechanism is a plausible explanation of the redistribution of con A receptors which we have observed (see ref. 7).

A crude estimate of receptor mobility can be made from the data on the time course of the redistribution. We take 2 h as the time needed for a receptor molecule to move approximately half way across the width of the cell, that is, the average electrophoretic mobility of the receptor is about 15 μm per 2 h per 4 ($V\ cm^{-1}$), or about $5\times10^{-4}\ \mu m\ s^{-1}\ (V\ cm^{-1})^{-1}$, a value 2×10^5 fold smaller than the electrophoretic mobility of a typical globular protein in an aqueous medium. The viscous drag experienced by the receptor molecules undergoing electrophoretic movement in the plane of the membrane is thus similar to that imposed by a medium having a viscosity of about 20 P (since the viscosity of water is 1 cP), which is close to but higher than other estimates of membrane viscosity[6]. Experiments on the relaxation of the asymmetry after the field is turned off suggest a diffusion coefficient for lateral diffusion of the mobile unlabelled receptor of $3\times10^{-11}\ cm^2\ s^{-1}$ (range $2–6\times10^{-11}\ cm^2\ s^{-1}$), since the diffusion coefficient, $D=r^2/2t$, where r is the radius of the cell ($\sim$15 μm), and t is the $1/e$ relaxation time[14]. This is a value comparable to those reported for mobile membrane proteins diffusing in the plane of the membrane[5,6,15–18].

The accumulation of con A receptors on the negative side of these muscle cells indicates that the majority of these molecules are either positively charged or else less negatively charged than other displaceable membrane components. This agrees with the finding of Skutelsky and Farquhar that the con A receptors of developing red blood cells have relatively little affinity for positively charged colloidal ion particles[19].

Finally, we expect that the *in situ* electrophoresis of cell surface components demonstrated in this report will prove to be a useful technique for measuring receptor mobility in the plane of the membrane and for exploring the molecular properties of cell-surface receptors within their natural membrane environment.

We thank Dr J. W. Vanable, Jr, for culture facilities, and the USNIH for a grant awarded to Professor Jaffe.

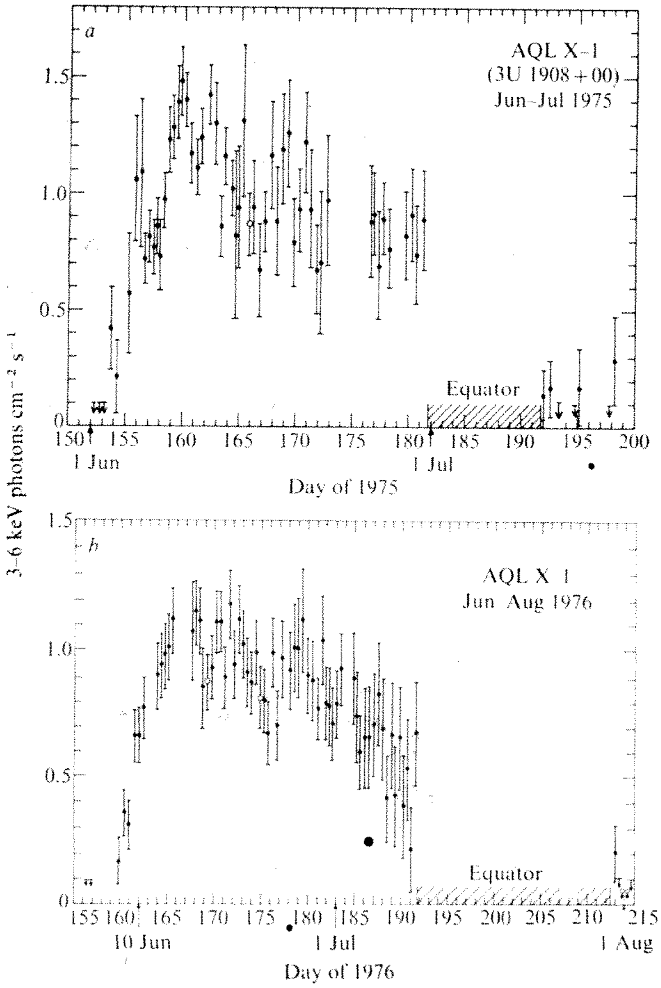
Recurrent X-ray outbursts from Aquila X-1

A HIGH degree of variability has been associated with Aquila X-1 (Aql X-1) (3U1908+00) since its occasional observation in early rocket surveys[1-3], and its appearance as a variable source of moderate brightness in the Uhuru catalogue[4] ($S \sim 0.07$–$0.2\, S_{\rm crab}$). Later observations of the source have been made from OSO-7 (ref. 5) during 1971–73 which suggest the existence of 'low' ($S \sim 0.02\, S_{\rm crab}$) and 'high' ($S \sim 0.5\, S_{\rm crab}$) intensity states, and from OAO Copernicus, where the source was reported at levels at least an order of magnitude below the Uhuru range during intermittent exposures over a 2-yr period through 1975 May (ref. 6). This apparent quiescent state was interrupted in 1975 June by a sudden flare[7] (factor of >20 increase) to the level of the Crab nebula. Observations of the declining source by the Sky Survey Instrument (SSI) on Ariel V revealed an ~10% sinusoidal modulation[8] (2–18 keV) at the period $P = 1.3 \pm 0.04$ d. By August the flux had decayed back to the pre-outburst intensity ($< 0.003\, S_{\rm crab}$) as measured by the SSI (ref. 9), which instrument observed the same low flux from Aql X-1 again in 1976 January. In 1976 June, the All-Sky Monitor (ASM) on Ariel V detected an additional outburst of this source[10], which was confirmed by the SSI (M. G. Watson, personal communication). We report here ASM observations of Aql X-1 obtained between the launch of Ariel V in 1974 October and 1976 November, and compare them with the previously cited additional data available. We suggest that the totality of these measurements imply that Aql X-1 may provide a plausible connection between dwarf novae and the very bright, long-duration transient X-ray source[11].

Fig. 1 ASM chronologies of the 1975 (*a*) and 1976 (*b*) flares of Aql X-1. The points are ~½-d averages, and the error bars are ±1σ (statistical error only). The shaded areas labelled 'equator' are times when Aql X-1 was close to the equatorial plane of the of the Ariel V satellite; during these times the source was inaccessible to the ASM, but observable by the SSI.



The proximity of Aql X-1 to the sources Ser X-1 (3U1837+04) and 3U1901+03 ($S_{\rm max} \sim 0.3\, S_{\rm crab}$ and $0.1\, S_{\rm crab}$, respectively) make unambiguous detection of a low Aql X-1 flux ($\lesssim 0.2\, S_{\rm crab}$) problematic in the ASM standard resolution mode (see ref. 12 for a complete experiment description). Consequently, occasional fluctuations in detector background and other systematic effects could conceivably result in 'accidental' flux measurements (with low probability) as high as $\sim 0.3\, S_{\rm crab}$ for this particular source. The data obtained during the 1975 and 1976 flares of Aql X-1 are illustrated in Fig. 1, and represent the only unambiguous detections of the source over the ~25 months of ASM operation during which the duty cycle for daily monitoring of the Aquila–Serpens region was >75%. These plots consist of ~½-d averages of the 3–6-keV flux (incident photons) with corresponding ±1σ statistical error bars (estimated 1σ systematic errors are smaller than the statistical uncertainties). The upper limits obtained ($0.1\ {\rm cm}^{-2}\,{\rm s}^{-1}$) immediately before the 1975 flare are consistent with the SAS-3 observations[7], and no positive detections of the source above $\sim 0.2\ {\rm cm}^{-2}\,{\rm s}^{-1}$ were made during the preceding 7½ months. A similar search of the ASM data over the period between the flares yielded no unambiguous source sightings through 1976 April, with a possible detection at $\sim 0.3\ {\rm cm}^{-2}\,{\rm s}^{-1}$ (for ~1 d) 2 weeks before the 1976 outburst. We note finally that the apparently differing peak flux levels of the flares are actually consistent with a single limiting value ($S_{\rm max} \approx S_{\rm crab}$), as degradation in the effective 3–6-keV detector efficiency of ~10% between the two flare observations cannot be excluded.

As a 1.3-d modulation has been reported[8] from the 1975 SSI flare data (obtained during the time interval in Fig. 1*a* labelled 'equator'), we have investigated both the 1975 and 1976 ASM data for periods in the range 0.3–3 d. The technique used consisted of separately folding the data over the range of trial periods and noting deviations in the χ^2-period distribution to the hypothesis of source constancy. The most prominent peak in the 1975 ASM data is, indeed, consistent with the SSI result. As the two experiments have mutually exclusive fields-of-view, the ASM result at a level of 3%±1% is an independent measure of the same effect, but cannot be claimed to be an independent detection owing to its marginal statistical significance. Assuming its reality, we can refine the period estimation to 1.28 ± 0.02 d. No such modulation is evident at this period in the 1976 data, however, with statistical errors comparable to those in 1975.

A summary of the totality of the 1971–76 data is displayed in Fig. 2, from which there is a clear indication that the OSO-7 data are consistent with flaring episodes similar to those in 1975–76. As there is no exact period which can be fitted to the four flares for which there is observational evidence, we have derived a mean flare interval of 435 d with an r.m.s. scatter of ~10%, and have indicated a possible history of identical flares which satisfy all of the observations.

The irregularity of the proposed flare cycle has several obvious implications for source models. In particular, Jones *et al.*[13] have recently reported recurrent flares from 3U1630−47 similar to those discussed here, but which exhibited a regular period of $P = 615 \pm 5$ d. Those authors have suggested that the 3U1630−47 flare cycle may represent the orbital period of an eccentric binary system (as has also been suggested for several transient sources[14,15]), but the observed scatter in the presumed Aql X-1 flare period is inconsistent with the relatively precise timing expected from binary phase-related variations in the accretion flow. The same consideration lessens the likelihood of an association of the present behaviour with a Mira Variable-type binary as proposed for the transients 3U1543−47 (ref. 16) and A1118−61 (ref. 18), or with a Her X-1—like precession-governed modulation[18,19] (as opposed to actual flares).

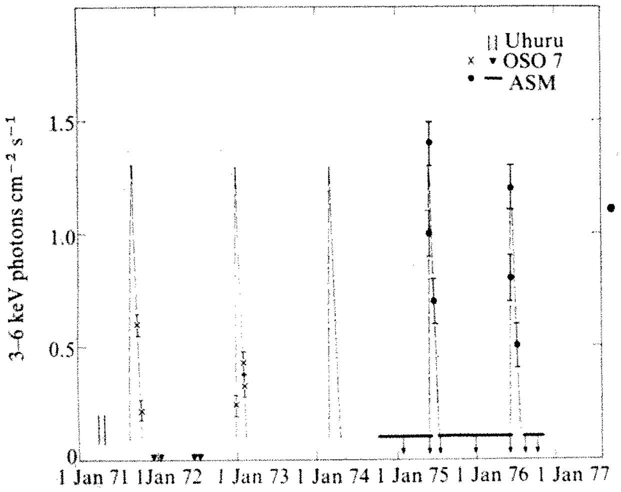


Fig. 2 Summary of Aql X-1 observations over the period 1971–76. The OSO-7 data is taken from Markert[5] and has been approximately converted to ASM units via normalisation with respect to the Crab nebula. Error bars in all data have been conservatively estimated to include possible systematic and normalisation errors. Intermittent Copernicus[6] measurements during 1973–75 (not displayed) are at the level ~0.01–0.02, and do not preclude a 1974 outburst as hypothesised.

We suggest that the observations are most easily interpreted in terms of an 'X-ray dwarf nova' binary of the type proposed by Avni, Fabian, and Pringle[20] for the transient source A0620–00, as the observed X-ray phenomenology is not unlike that of the optical light curves of dwarf novae (and some recurrent novae). Using the empirical period–amplitude relation of Payne-Gaposchkin[21] for U Gem stars and recurrent novae, the inferred luminosity ratio $L_{max}/L_{min} \sim 500$ (assuming that most of the radiation emerges in X rays) yields an expectation value for the interval between flaring episodes of ~465 d. The excellent agreement between the predicted and observed mean flare cycles should not be taken literally, as the uncertainty in L_{max}/L_{min} implies a correspondingly wide dispersion in the expectation flare interval. Furthermore, X-ray dwarf novae may deviate significantly from period–amplitude relations describing their optical analogues[20,22], so we can conclude only that the observed flare interval is not inconsistent with that which might be expected from such a source. The close similarity of the two ASM flare light curves is another model constraint, as it suggests detailed reproduceability. This characteristic of the source behaviour can be reconciled with accretion dwarf nova models invoking relatively continuous mass transfer to an accretion disk which is eventually 'dumped' by an instability[23] or, alternately, quasi-periodic unstable Roche-lobe overflow of the red star[22]. In the former model, the similarity of the flares results from the comparable amounts of material accumulated between episodes, while in the latter a high regularity of the magnitude of Roche-lobe spills and/or a feedback loop (regulated first by self-excited transfer and later by Eddington-limited flow) may be implied. Finally, we note that the non-flaring source behaviour observed by Uhuru (C. Jones, personal communication) may be analogous to the 'standstills' observed in several dwarf novae including Z Cam[23] ($S_{standstill} \sim 0.3$–$0.5\ S_{max}$).

The similarity of the Aql X-1 flares reported here to the more extreme episodes of the transient X-ray sources has been pointed out by several observers[8,24]. The abrupt ($\lesssim$ 1 week) rise by ~2 order of magnitude and subsequent gradual nova-like decay (*e*-folding time ~1 month) back to the pre-flare level are reminiscent of the characteristic transient source light curves, apparently differing only in the degree of brightening (L_{max}/L_{min} for transients is, by definition, $\gtrsim 10^3$) and the absence of a clear precursor peak. This behaviour is, on the other hand, qualitatively different from the recurrent flares of Cyg X-1 (ref. 26) or the extended 'highs' (sometimes lasting for hundreds of days) exhibited by sources such as Cen X-3. In the context of a transient source association for Aql X-1, we note that the relatively soft flare X-ray spectrum[6] suggests a generic relation to the class of 'long-duration' transients[11] (for example, A0620−00 A1524−62, and A1742−28), as opposed to the harder-spectral, shorter-lived transients exemplified by A1118−61 and A0535+26. The identification of the transient A0620−00 with a recurrent nova[26] and the resemblance of the long-term behaviour of Aql X-1 to both the transient X-ray sources and dwarf novae suggests that at least some members of the former group may arise from systems similar to the latter, but with the blue-dwarf binary component replaced by a neutron star or black hole.

We thank R. Rothschild for bringing the availability of the OSO-7 observations to our attention. L. J. K. acknowledges support from the University of Maryland.

Variability of the BL Lacertae object AO0235+164

WE can summarise previous[1-3] discussion of the problem of excessive Compton scattering in variable compact non-thermal sources by saying that the small size implied by rapid variability leads to too large a probability that a given electron will Compton-scatter one of the emitted photons, leading to an excessive X-ray flux. The basic assumptions underlying these difficulties are that the time-variable radiation is produced by the incoherent synchrotron process by electrons with large pitch angles in randomly oriented magnetic fields, and that the objects are at the cosmological distances implied by their redshifts. We present here a crude model of the recently observed outburst[4] of AO0235+164 in the near infrared and visible, where variability of up to 30% on time scales of 1 or 2 d has been noted. In our model the assumptions of large pitch angle and randomly oriented fields are relaxed[5] and the model accords with our previous discussion[3] of the low-frequency variability of the radio sources 3C454.3 and CTA 102.

The general picture is that of a strong dipolar magnetic field, with field lines of radius of curvature ρ, which is anchored to a spinning massive object, or 'spinar'. Electrons are accelerated by strong electric fields[6] near the surface of the 'spinar', where $E{\cdot}B \neq 0$. They move freely along the magnetic field lines and acquire large momentum components parallel to B.

The observed 1–10-d variability of AO0235 in the near infrared and visible is then due to a burst of electrons of dimension $l \approx ct_V$, where t_V is the observed variability time scale, passing through a region of the magnetosphere in which the magnetic field is nearly tangent to the line of sight to the observer. The beaming angle θ of the burst is either the pitch angle φ of the electrons or the quantity l/ρ, whichever is greater. We show that for the parameters considered here $\varphi < l/\rho$, so that $\theta \approx l/\rho$. Rieke *et al.*[4] find that if the radiation at and near 10^{13} Hz were isotropic and at a distance given by the redshift 0.852, the luminosity in this spectral region would be 10^{47} erg s^{-1}. However, the small beaming angle θ implies that the total luminosity is actually $L_{IR} \approx 10^{47}\theta^2/4\pi \approx 10^{41}\, t_D{}^2/\rho_Y{}^2$, where ρ_Y is the magnetic field line radius of curvature in light years, and $t_D = (86{,}400)^{-1}\, t_V$ is the variability time scale in days. The synchrotron power output of a single electron is $P_{syn} \approx 2\times10^{-15}B_\perp{}^2\gamma^2$ erg s^{-1}, where $B_\perp = B\sin\varphi \approx B\varphi$, in gauss, and γ is the Lorentz factor of the electrons. If N is the relativistic particle density, we have $L_{IR} \approx Nl^3P_{syn}$, and therefore

$$N\gamma^2B_\perp{}^2 \approx 1.5\times10^9\, t_D{}^{-1}\,\rho_Y{}^{-2} \tag{1}$$

The synchrotron lifetime t_{syn} of the particles must be long enough for us to stand a reasonable chance of seeing them. With $t_{syn} \approx 20/(B_\perp{}^2\gamma)$ in yr, $t_{syn} > \rho_Y$ implies

$$B_\perp{}^2\gamma < 20/\rho_Y \tag{2}$$

Also, the electrons must radiate at predominantly 10^{13} Hz. Since we are interested in small pitch angles, we must remember that the usual expression for the 'critical frequency' ν_c for synchrotron radiation holds rigorously only for $\gamma\varphi \gg 1$. But for our purposes, it sufficies to set $\nu_c \approx 6\times10^6B_\perp\gamma^2$ Hz for $\gamma\varphi > 1$. The very small pitch angle case ($\gamma\varphi < 1$) seems to be ruled out because of the high linear polarisations observed[4], which are of the order of 10%. We set $\nu_c = 10^{13}$ Hz to obtain

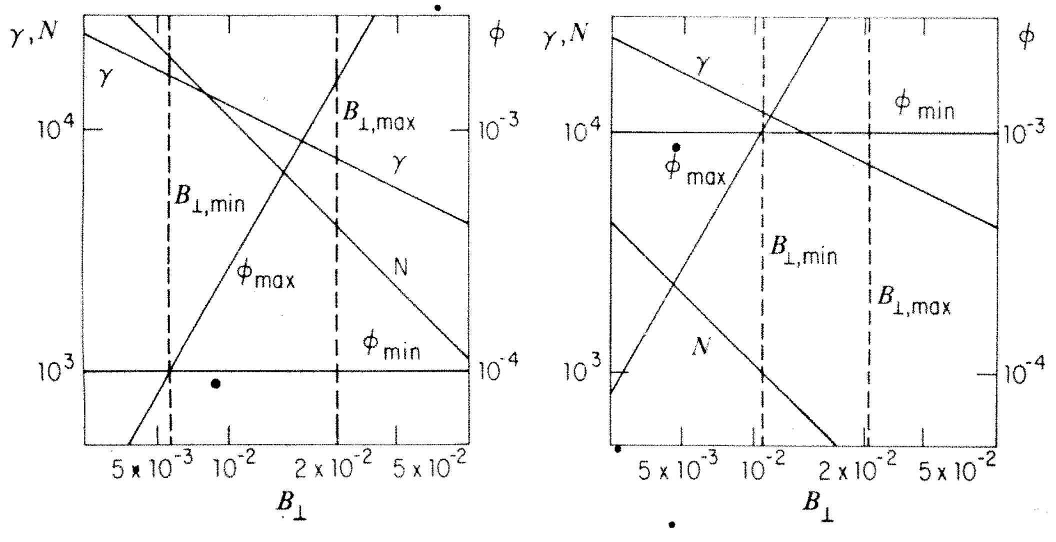
$$B_\perp\gamma^2 \approx 1.6\times10^6 \tag{3}$$

According to Epstein, small[7] pitch angles give linear polarisations $P \lesssim \theta_R/\theta_B$, where θ_R is the angular width of the radiation about the magnetic field lines, so that $\theta_R \approx \varphi + \gamma^{-1}$, and θ_B is a measure of the angular dispersion of the field direction in the source. But θ_B is just our 'beaming angle,' and so we have $P \lesssim (\varphi+\gamma^{-1})/(l/\rho) \approx 300\varphi\rho_Y/t_D$, since $\gamma\varphi > 1$. The observed $P \approx 0.1$ then implies

$$\varphi > 3\times10^{-4}\, t_D/\rho_Y \tag{4}$$

We must now address the problem of excessive Compton-scattered X-ray flux, wherein we require the Compton-scattered X-ray luminosity L_{XR} to be less than L_{IR}. This is more restrictive than requiring the source to be undetected by Uhuru. We are aided by the fact[3,5] that if ψ is the angle between the initial momenta of the electron and photon, the final scattered photon frequency is $\nu_{XR} \approx 2\,\nu_{IR}\,\gamma^2\sin^2(\tfrac{1}{2}\psi)$, and one can show[3] that $L_{IR} > L_{XR}$ implies $1/8N\sigma_T\, l\gamma^2\psi^4 < 1$, for small ψ, where $\sigma_T \approx 6\times10^{-25}$ cm^2 is the Thompson cross section. ψ may be estimated by assuming that the field lines are concentric circles and then demonstrating geometrically that an average ψ is given by $\cos\psi = \rho\cos\varphi/(\rho+1/2l)$, or $\psi^2 \approx \varphi^2 + l/\rho$. But

Fig. 1 The parameters of the model of AO0235+164 variable with a timescale of 1 d (left) and 10 d (right) for a magnetosphere of the size of 1 pc ($\rho_Y = 3$).



since, as we have said, $\varphi < l/\rho$, it follows that $\psi^2 \approx l/\rho$, and therefore the Compton-scattering condition becomes

$$N\gamma^2 < 5\times10^{14}\rho_Y^{2}t_D^{-2} \qquad (5)$$

There is one final constraint that we might impose. Since we wish the general shape of the magnetosphere to remain intact, we require that the magnetic field energy density be greater than the relativistic electron energy density in the burst, or $B^2/4\pi > N\gamma mc^2$. This gives

$$B^2 > 10^{-8}\,N\gamma \qquad (6)$$

The relations (1)–(6) represent six constraints on the five unknowns $B_\perp$, φ, N, γ and ρ_Y (t_D is an observed quantity). From these conditions we obtain the following restrictions on the magnitudes of the parameters $B_\perp$, φ, N and γ as functions of ρ_Y and t_D:

$$1.8\times10^{-4}\,t_D\rho_Y^{-2} < B_\perp < 6\times10^{-2}\,\rho_Y^{-2/3} \qquad (7, 8)$$

$$3\times10^{-4}\,t_D\rho_Y^{-1} < \varphi < 1/3t_D^{1/2}\,\rho_Y B^{7/4} \qquad (9, 10)$$

$$1.7\times10^{4}\,t_D^{-1}\rho_Y^{-4/3} < N < 1.7\times10^{6}\,t_D^{-2} \qquad (11, 12)$$

$$5\times10^{3}\,\rho_Y^{1/3} < \gamma < 3\times10^{4}\,t_D^{-1/2}\,\rho_Y \qquad (13, 14)$$

The inequalities (7) and (8) are obtained from (5) and (2), respectively, by using (3) to express $\gamma \approx 1.3\times10^3 B_\perp^{-1/2}$ and then substituting into (1) to get $N \approx 10^3 t_D^{-1}\rho_Y^{-2}B_\perp^{-1}$. The inequality (9) is just (4), and (10) follows by writing (6) as $\varphi = B_\perp/B < B_\perp(10^{-8}N\gamma)^{-1/2}$ and then substituting for N and γ. The inequalities (7, 8) and (9, 10) are necessary and sufficient conditions for the validity of the model. We have left ρ_Y as an 'external' parameter, since we wish to choose a value for it which is not much different from that in the authors' model[3] for 3C454.3 and CTA 102, where $\rho_Y = 1$.

Careful focus on a typical situation ($\rho_Y = 3$) is depicted in Fig. 1, where the various parameters are presented now as functions of $B_\perp$. The allowed ranges of $B_\perp$ are indicated by dashed lines. Solid lines show the corresponding values of N and γ, and the ranges of the pitch angles φ. The model 'preconditions' $\gamma\varphi > 1$ and $\varphi < l/\rho \approx 3\times10^{-3}t_D/\rho_Y$ are satisfied here.

Thus we see that our crude model, with $\rho_Y = 3$ typically, provides a description of the observed outbursts of AO0235 in the near infrared and visible, with total magnetic fields $B = B_\perp/\varphi$ between 10 and 200 G, electron pitch angles between 10^{-4} and 10^{-3}, and Lorentz factors of 10^4. The magnetosphere is thus about 1 pc in size, which gives total magnetic field energies $B^2\rho^3$ of 3×10^{57}–10^{60} erg, or between 10^3 and 3×10^5 solar rest masses. Total burst energies $N\gamma mc^2l^3$ run between 3×10^{47} and 10^{51} erg.

Since the beaming angle is only 1–10 mrad, we would observe only about one event out of every 1,000. Correspondingly, outbursts of this sort are not often observed. A rough upper limit to the total output of AO0235 can be made by assuming that we observe one event every 10 yr, with a real rate of 100 yr^{-1}. If each outburst has an energy of 10^{49} erg, the average output is 3×10^{43} erg s^{-1}, which is a typical quasar radio luminosity.

The question arises whether synchrotron radiation losses near the surface of the spinar, where the magnetic is much stronger, can substantially exceed the radiated energy in the outer magnetosphere, given by equation (1). A cursory calculation indicates that this is no problem, as long as the magnetic field does not exceed 10^6 G at the surface, taken to be 3×10^{16} cm from the centre[5]. If the field is not accurately dipolar near the surface, but is proportional to r^{-1} or r^{-2} there, there is no conflict with our choice of $\rho_Y = 3$. However, if the field is accurately dipolar, then a model with $\rho_Y = 0.3$ can be shown to be satisfactory.

With such a highly anisotropic electron distribution in pitch angle, there might be problems with instabilities caused by generation of Alfvén waves in a thermal background plasma. This might very well have been the case in the early evolutionary stages of the magnetosphere. The coupling between the Alfvén waves and the beams of relativistic electrons would, on the other hand, mean that the thermal plasma would pick up momentum from the beams, and eventually be swept out of the magnetosphere. After a sufficiently long time, the magnetosphere would be practically evacuated and no further significant Alfvén wave production could occur. Our paper is concerned only with this latter phase.

Our model could also resolve the problem of the low-frequency variability of such radio sources as 3C454.3 and CTA 102, although coherent particle bunching is required. Cocke and Pacholczyk[3] used $\rho_Y = 1$ for these sources. Equally important, Sanders[7] has shown that this general picture is capable of explaining in a natural way the apparent superrelativistic separation of the components of multiple radio sources, such as revealed by recent observations of 3C345 (ref. 9). Small pitch angles are necessary to Sander's discussion also, and expansion along the same direction in successive outbursts is provided by the stable orientation of magnetic axis.

Uranus occults SAO158687

ON March 10, 1977, Uranus will occult SAO158687, a star of late spectral type with a visual magnitude of ≈ -9.5 (refs 1,2). The occultation will be visible from land areas surrounding the Indian Ocean[1,2]. From high-quality light curves of this event one can obtain temperature, pressure and number density profiles of the uranian atmosphere; information about its composition; and by combining occultation timings from several stations the precise diameter and oblateness of the planet can be found. For the atmospheres of Jupiter[3–5] and Mars[6–9] these quantities have been obtained from recent stellar occultations by these planets. This experience can be used to predict what can be learned from the forthcoming occultation by Uranus.

Although Uranus is several magnitudes brighter than SAO 158687 at visual wavelengths, the strong methane absorption bands in the far red and infrared spectrum of Uranus make the intensity of both objects nearly equal at these wavelengths[3]. To see how to use the methane absorption bands to best advantage, we obtained the spectra of Uranus and SAO 158687 (Fig. 1). These spectra are meant to show the relative instrumental intensities of the two objects and have therefore not been calibrated on an absolute scale. The resolution of the spectra is 10 Å and the cutoff near 9,000 Å is due to a cutoff in

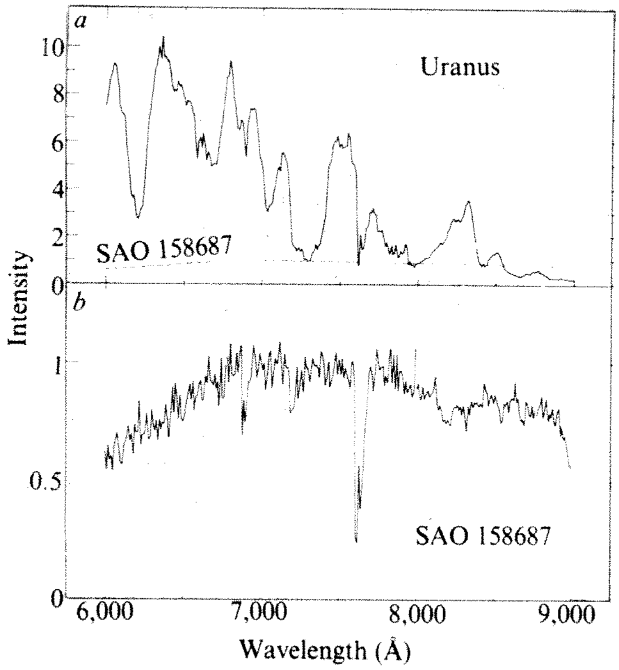

Fig. 1 Relative intensity of Uranus and SAO158687. Each spectrum was obtained with a 10-Å slit; the intensity scales are linear in the instrumental system. *a*, The two spectra on a common scale; *b*, an expanded version of the SAO158687 spectrum. In the deep methane band near 8,600 Å the stellar flux exceeds that of Uranus. The common absorption feature near 7,600 Å is the telluric Fraunhofer A band of molecular oxygen.

the instrumental response. The contribution from the sky background and dark current is negligible.

Table 1 lists four passbands where the relative intensities (integrated over the passband) of SAO158687 and Uranus are most nearly equal. Since the passbands are narrow, the ratio of these intensities is, for practical purposes, equal to the ratio of the photon fluxes f_*/f_u, where f_* and f_u are the photons cm^{-2} s^{-1} Å^{-1} incident on the Earth's atmosphere from SAO158687 and Uranus, respectively. We have assumed SAO158687 to have UBVRI colours appropriate for a K5 main sequence star[1,2,10] and computed the expected photon fluxes f_* (Table 1).

If observing conditions are good during the occultation, then the signal–noise ratio of the light curves should be limited by photon statistics. The latter give a fundamental limit for the signal–noise ratio achievable. We define $\varphi(t)$ to be the flux from SAO158687 observed during the occultation, normalised to the unocculted intensity of the star. Hence $\varphi(t)$ begins at 1.0 and decreases to 0.0 as the occultation proceeds. If ε_φ is the r.m.s. error in φ due to photon statistics for a 1-s integration, then ε_φ is equal to the square-root of the total photons detected from Uranus and the star, divided by the photons that would have been detected from the unocculted star

$$\varepsilon_\varphi = \frac{(\bar{\varphi} f_* + f_u)^{1/2}}{f_* \sqrt{(q \Delta\lambda A)}} \qquad (1)$$

where $\bar{\varphi}$ is the average value of $\varphi(t)$ during a 1-s interval, A is the area (cm^2) of the telescope, $\Delta\lambda$ the passband of the filter (in Å) and q the fraction of the photons incident on the Earth's atmosphere that are ultimately detected by the photomultiplier. The factor q includes the transmission of the Earth's atmosphere, telescope optics, photometer optics and the quantum efficiency of the photomultiplier. The quantity ε_φ has the dimensions of s$^{1/2}$, the actual r.m.s. error in φ for an arbitrary integration time of Δt s is found by dividing ε_φ by $(\Delta t)^{1/2}$. In writing equation (1) we assume that the background counting rates from the photomultiplier itself and the sky are negligible. This may not be entirely true, since a quarter Moon will be only 17° away[1] during the occultation.

Values of ε_φ (Table 1) were computed for $\Delta t = 1$ s, $q = 0.04$, $A = 6.6 \times 10^3$ cm^2 (36-inch telescope) and $\bar{\varphi} = 1/3$.

From Table 1 we see that low photon noise errors can be achieved by choosing appropriate passbands for observation. Such low errors could be realised in ideal conditions, but in practice changes in transparency, guiding errors, severe scintillation[12] and other problems could increase the effective noise in the signal above the level of photon noise.

From the photon noise levels in Table 1, we can calculate the r.m.s. error expected for the temperature profiles obtained from the occultation light curves, if we assume that the gravity gradient model[3] applies to the uranian atmosphere. From the improved procedure of French *et al.*[11] for obtaining temperature profiles from occultation light curves, the minimum r.m.s. error in the scale height $\sigma(H)$, expressed as a fraction of the scale height H is

$$\left.\frac{\sigma(H)}{H}\right|_{\min} \approx 1.5 \left(\frac{v_\perp}{H}\right)^{1/2} \varepsilon_\varphi \qquad (2)$$

where $v_\perp$ is the apparent velocity of SAO158687 perpendicular to the limb of Uranus. The scale height is related to the temperature T by $H = RT/\mu g$, where g is the gravitational acceleration, R the universal gas constant and μ the mean molecular weight of the atmosphere. At the occultation level we expect $T \sim 140$ K (ref. 13), hence $H \sim 65$ km (for $\mu \sim 2$). For this occultation $v_\perp \sim 12$ km s^{-1} (ref. 2). Even for the largest value of ε_φ in Table 1 (0.04), the fractional error in the scale height is only 2.6% (equation (2)). The minimum error in the temperature then will probably be dominated by uncertainties in the mean molecular weight.

At the occultation level the main constituents are likely to be H_2, He and CH_4. For solar composition the mixing ratio of CH_4 would be $\sim 7 \times 10^{-4}$ (ref. 13), which would leave H_2 and He as the major constituents. It may be possible to obtain a value for the helium number fraction [He]/[H_2], from light curves at two wavelengths (6,200 and 8,600 Å, for example), as was done for Jupiter[14], and for the [Ar]/[CO_2] fraction in the case of Mars[9]. *A priori*, it is difficult to predict the expected accuracy of this measurement, since the accuracy will depend on the number and intensity of the 'spikes' in the light curves[3].

The level of the atmosphere probed by the occultation corresponds to a number density n given approximately by the number density at 'half-light' for an ideal isothermal atmosphere[15]

$$n = \frac{\mathscr{L}}{\nu_{STP}} \left(\frac{T}{273\text{ K}}\right)\left(\frac{H}{D}\right) \frac{1}{\sqrt{2\pi (R_p/H)}} \approx 6 \times 10^{13} \qquad (3)$$

where $\mathscr{L}$ is Loschmidt's number, ν_{STP} the refractivity of the

atmosphere at STP, D the distance to Uranus and R_p the radius of Uranus.

The 'central flash', observed during the occultation of ε Gem by Mars[16], and used to determine the extinction of the martian atmosphere[9], will probably not be observable, since the centre of the Uranus shadow is predicted to be off the edge of the Earth.

Observers of this occultation should record their data digitally. The shortest timescale of importance for the 'spikes' will be $\sim \delta D/2v_1 \approx 0.3$ s, where $\delta = 5.8 \times 10^{-4}$ arc s (ref. 2) is the angular diameter of SAO158687. Higher time resolution data recording would be desirable, but is not essential.

We plan to observe this occultation from Perth and over the Indian Ocean with the 91-cm airborne telescope[16]. Observers of this occultation interested in coordinating the analysis of their results should write to one of us. We acknowledge the support of grants from NASA.

Note added in proof: An updated prediction for this occultation can be found elsewhere[17].

Predicted and observed coronal structure

THE total eclipse of the Sun of October 23, 1976 was observed in excellent conditions from Victoria (Australia). The observation programme was designed to study the shape and structure of the corona; this structure is caused by magnetic fields. The corona's shape generally undergoes changes that follow the 11-yr cycle of solar activity. At the time of the eclipse the Sun's activity was near its minimum. In July the mean sunspot relative number was 2.1, in August 16.9, in September 13.4, in October 21.8, and in November 5.5. In these months the activity of the old cycle was still stronger than that of the new one, except in October. The high number of that month was produced mainly by the new cycle. It is not yet certain whether the minimum had been reached by the time of the eclipse. In any case, solar activity was low, but stronger than during most of the earlier minima. Therefore a typical 'minimum-corona' was to be expected, but not the shape of the 'undisturbed corona'. This shape is seldom observed, and was last seen on June 30, 1954, when the Sun was almost completely free of spots for three months before the eclipse[1].

The corona of October 23, 1976, consisted of two main parts completely different in character—a belt of large streamers, going up to heliographic latitudes of $b = 60°$, and the polar regions. As well as some weaker features, there were four large, broad and bright streamers, one in each of the four quadrants. Prominences were found at the base of these streamers, at $b = +41°$ and $-35°$ on the E-limb and at $b = -43°$ on the W-limb. The least developed of the four main streamers was that of the NW-quadrant, in which no prominence was observed. The axes of the streamers deviated strongly from the radial direction and were more or less parallel to the Sun's equator. On the poleside the streamers had a sharp edge. The heliographic latitude of that edge, measured at the Sun's limb, was $+64°$ in the NE-quadrant, $-55°$ in the SE-quadrant, $-60°$ in the SW-quadrant and $+46°$ in the NW-quadrant.

The polar regions were less bright than the main streamers. Each of the two polar cups contained a bundle of about 20 short and narrow streamers, the so-called polar plumes. Around the solar axis their direction was radial, becoming more and more inclined as the polar distance increases.

As the shape of the streamers is formed by the magnetic fields, K. H. Schatten attempted to predict the structure of the corona using the photospheric magnetic fields measured at the Hale Observatories (Mt Wilson) between September 13 and October 10. The result, a computer-drawn plot made on October 18 (ref. 2), is compared with the observations in Fig. 1, which is a sketch of the corona's structure based on photographs obtained at the eclipse. Generally the agreement between observed and predicted patterns is satisfactory. One huge equatorial streamer was predicted for both the east and the west limbs of the Sun, as could be expected for an 'undisturbed' corona. In fact, there were two streamers on each limb, one in each hemisphere, representing the 'minimum-type' rather than the 'undisturbed' corona. The dipolar field represents the polar plumes well. The positions at which the edges of the long streamers limit the polar regions were correctly predicted for the NE- and SW-quadrants. In the SE- and SW-quadrants, however, the observed heliographic latitude of the edges was about 20° smaller than the prediction.

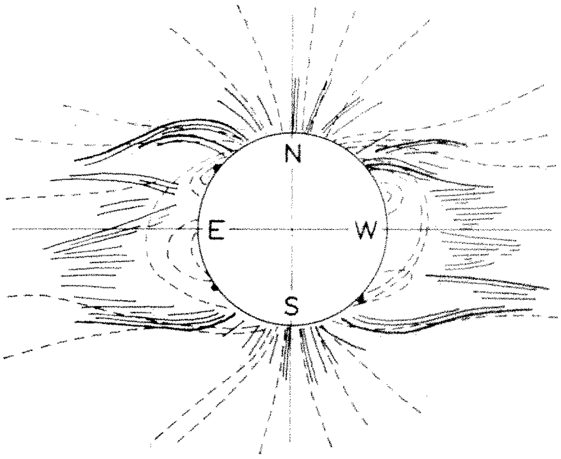

Fig. 1 The structure of the corona at the solar eclipse of October 23, 1976. Observations are represented by solid lines and predictions by dashed lines.

Improved and extended theory of the Berthelot tube method of studying liquids under tensile stress

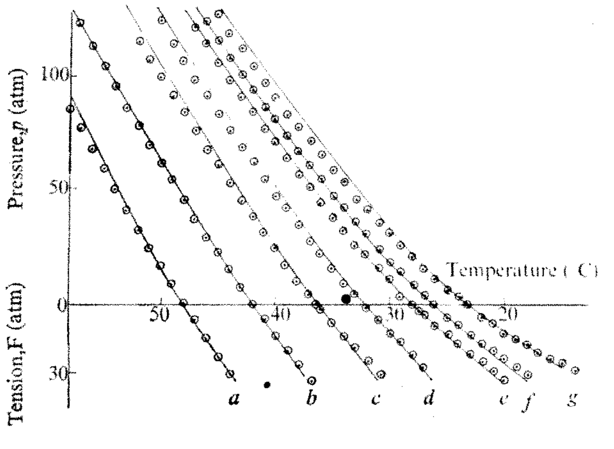
ALTHOUGH the Berthelot tube method of subjecting a liquid to tension has been used intermittently for several years, there is no published theory which enables us to calculate the value of the tension at any stage before the breaking, that is, rupture of the enclosed liquid. We present here such a theory, giving good agreement with the experimental values of the tension obtained directly using a transducer method. In the past, two theories of the method have been given but these only enable us to calculate values of the breaking tension; first, the theory of Vincent and Simmonds (method 1), which we shall show to contain a serious error and second, that of Temperley and Chambers (method 2). These two methods have been discussed by Chapman *et al.*[1].

A liquid can withstand tension due to its ability to exist in a metastable phase. This has applications in work on cavitation, in the design of such things as ship propellers and in the field of lubrication. In its metastable phase a liquid is superheated and this is the basis of the bubble chamber where the path of an ionising particle is shown as a trail of vapour bubbles as it passes through a superheated liquid; the ions produced by the high energy particle act as nuclei on which these bubbles can form. Columns of sap rise to the top of very tall trees due to the existence of tension in the sap column; tensions of > 50 atm have been found in mangrove trees.

The Berthelot tube method is as follows. A sealed tube, usually of glass or steel, is almost completely filled with the test liquid while the remaining volume is occupied by air and liquid vapour. On heating, the liquid expands to fill the whole tube and positive pressures are generated in the liquid. If, next, the tube is allowed to cool slowly, the liquid continues to fill the tube and adhere to its inside walls; during cooling the positive pressure inside decreases to zero and then changes to a negative pressure (tension) until the liquid eventually breaks with the onset of cavitation. At this 'break' there is a sudden increase in the volume of the tube as the internal tension is released. Richards and Trevena[2] have followed these pressure changes directly using a pressure transducer and have obtained some experimental (pressure, temperature, that is) (p,T) curves for water (Fig. 1).

Our proposed theory is as follows. If we consider one of these (p,T) curves (say curve a) then the point on the curve where the pressure is zero corresponds to the state in which both the tube and enclosed liquid are in an unstressed condition. Let V_0 and T_0 be respectively the internal volume of the tube and the temperature at this stage (stage 1). The tube and its contents are then cooled so as to follow the curve to a lower temperature in the tension region where the internal volume of the tube is V_1 and the temperature T_1 ($< T_0$) (stage 2). At this stage tension F is generated in the enclosed liquid and both the liquid and tube are in a state of stress. At this stage we then consider what the unstressed volumes of the liquid and tube would be at the existing temperature T_1. The unstressed volume W_1 of the liquid would be $< V_1$ and the unstressed volume of the tube would be $V_1 - \Delta V_1$ (stage 3). (This is precisely what would happen if the enclosed liquid were to actually break at T_1.) We let ρ_0 and ρ_1 denote the densities of the unstressed liquid at the temperatures T_0 and T_1 (stages 1 and 3, respectively).

Fig. 1 Full lines: experimental (p,T) curves obtained by Richards and Trevena for water in a steel Berthelot tube. ⊙, F and p values calculated using the present theory.



For the unstressed liquid in stages 1 and 3

$$V_0\rho_0 = W_1\rho_1 \qquad (1)$$

Next consider stages 2 and 3 for the liquid at T_1. The volume of the liquid is V_1 under a tension F and W_1 under zero tension ($W_1 < V_1$). Thus, if K_1 is the bulk modulus of the liquid

$$K_1 = -\frac{F}{(V_1 - W_1)/W_1} \qquad (2)$$

Similarly, let us consider stages 2 and 3 for the tube at T_1. Its inside volume is V_1, under an internal tension F, increasing to $V_1 - \Delta V_1$ under zero internal tension, when the liquid breaks. Thus, if K_s is the bulk modulus of the material of the tube,

$$K_s = -\frac{F}{\Delta V_1/(V_1 + \Delta V_1)} \qquad (3)$$

Finally, we consider stages 1 and 3 for the tube; since the tube is unstressed in both cases,

$$V_1 + \Delta V_1 = V_0(1 - 3\alpha\Delta T_1) \qquad (4)$$

where $\Delta T_1 = T_0 - T_1$ and α is the linear coefficient of expansion of the material of the tube.

Equations (1) – (4) give the 'basic physics' of the method and can be solved to give an expression for the tension F

$$F = \frac{\rho_0/\rho_1 - (1-3\alpha\Delta T_1)}{\rho_0/\rho_1 K_1 - (1-3\alpha\Delta T_1)/K_s} \qquad (5)$$

in terms of the known or measurable quantities α, ΔT_1, ρ_0, ρ_1, K_1 and K_s.

Suppose that we return to our initial stage 1 and move up the curve a of Fig. 1 to a point in the pressure region; let the pressure inside the tube at this stage be p and the corresponding temperature T_2 ($> T_0$). We can then obtain a value for the pressure p generated inside the tube at the temperature T_2

$$p = \frac{(1 - 3\alpha\Delta T_2) - \rho_0/\rho_2}{\rho_0/\rho_2 K_1 + (1 + 3\alpha\Delta T_2)/K_s} \qquad (6)$$

where $\Delta T_2 = T_2 - T_0$ and ρ_2 is the density of the unstressed liquid at the temperature T_2.

The present theory enables us to calculate the tension or pressure in the enclosed liquid at any stage of the process, using equations (5) and (6), thus improving on previous theories of the Berthelot method which only give an equation for the value of the actual breaking tension.

From integral values of ΔT_1 and ΔT_2 we can compute the values of F and p from equations (5) and (6) using the appropriate values of the other quantities involved as obtained from tables. These calculated values are shown in Fig. 1 and the agreement between theory and experiment is satisfactory.

In method 1, Vincent and Simmonds write

$$V_b = V_f[1-3\alpha(T_f-T_b)] \qquad (7)$$

where V_f is the volume at the filling temperature T_f and V_b that immediately after the break at the temperature T_b when the tube is in an unstressed state. But an equation such as (7) can only be applied provided the tube is in the same state of stress at both T_f and T_b. Chapman *et al*[1] have, however, shown that pressures of 50–100 atm exist in a Berthelot tube at T_f. Thus the theory of method 1 is incorrect since it only takes into account volume changes due to temperature differences and ignores those due to the change in the state of stress of the tube; our theory takes both of these factors into account. Method 2 predicts values for the breaking tension which agree quite well with the experimental values obtained directly from the transducer measurements of Richards and Trevena. One great advantage, however, of our theory is that equation (5) enables us to calculate the tension inside the tube at any stage before rupture; methods 1 and 2 only enable us to calculate the values of the actual breaking tension (and method 1 does that incorrectly). Also, our theory is in satisfactory agreement with experiment, in both pressure and tension regions (Fig. 1)

We hope that we have corrected some previous errors, and both extended the Berthelot tube theory and put it on a firmer foundation.

We thank Dr W M Jones for comments and suggestions

Ion-pair clusters and excited-state yields in radiolysis

WHEN β or γ rays are absorbed in matter, sparse tracks of ion pairs are produced. the secondary electrons sometimes have enough energy to produce further ion pairs in small clusters Distributions of cluster size in a cloud chamber were measured by Wilson as long ago as 1923 (ref 1); reinterpretation[2] of his and other results shows that nearly two thirds of the ion pairs occur in clusters. Similar behaviour should occur in other phases, but little is yet known of the role of clusters in radiolysis In hydrocarbons, the geminate recombination of radical ions is a major process: most theoretical descriptions have dealt only with single ion pairs[4]. Since most of the ion pairs recombine very quickly, the clusters will rapidly become single pairs, so the approximation is probably quite good for scavenging studies. If we consider recombination products, especially the yields of singlet and triplet excited states, cluster formation must be taken into account[4]

Measurements made by pulse radiolysis[5–7] of yields of excited singlet and triplet states, $^1M^*$ and $^3M^*$, in alkanes and benzene derivatives containing added aromatic hydrocarbons (M) have shown triplet-to-singlet ratios, T/S, ranging between 1 and 2. Hereafter 'triplet' and 'singlet' will usually refer to the ion pairs Though the ions are so far apart (~50–100 Å) for most of the life of a pair that the unpaired electrons do not interact, one can still speak of singlet or triplet character[8,9].

A single ion pair will normally be formed in a singlet state if recombination is fast enough, only $^1M^*$ will be produced[8] Single triplet pairs will be formed if the secondary electron has sufficient energy to excite another molecule to a triplet state by electron exchange[4] (process A). In clusters, some triplets will be formed by cross-recombination (process B). Calculation of T/S for B is a surprisingly difficult mathematical problem; however, combining the results of Atkins and Lambert[10] with the spur size distribution[3] gives 0.34.

Initial spin correlation in an ion pair will decay over some tens of nanoseconds[8]; the rate of decay and its final extent can be changed by magnetic fields[8,9]. In the simple case of a single pair, initially singlet, the final state at zero field consists of one quarter singlets, three quarters triplets. in a strong magnetic field, the singlet can only interact with T_0· the T± components become inaccessible because of their Zeeman energy: the final state is half singlet, so the field should increase the yield of $^1M^*$ and of fluorescence by a factor of 2 at long times.

By the single-photon counting method, I measured scintillation pulse shapes for solutions of *para*-terphenyl, anthracene (and their perdeutero-analogues), biphenyl and perylene in a number of alkanes and benzene the enhancement ratios at long times (~100 ns after ionisation) are in the range 1.30–1.45 for alkanes· there is little or no dependence on the nature of the solute. These are tentative figures. the limiting values may not be reached, or the yields of $^1M^*$ and $^3M^*$ may be influenced by energy level densities (Frank–Condon factors)[8]. However, in both cases one would expect to see differences between solutes. Therefore, I propose that these low values are due to scavenging of initially triplet ion pairs. Triplets decay into singlets reducing the net effect; if the initial T/S were 3, there would be no net change and the field effect would disappear: the above range corresponds to initial T/S ratios between 1 1 and 0.7 This interpretation is supported by the case of benzene solutions, where the enhancement is only 1.09 (T/S ~ 2.15). The benzene triplet state lies well below those of the alkanes, so that process A will be more important

Total yields of $^1M^*$ and $^3M^*$ (refs 5–7) are less easy to interpret: the excitation mechanisms are still being debated; in particular it has been proposed[6] that singlet excitation transfer from the solvent is the main source of $^1M^*$ rather than ion recombination[7] Also, ion recombination is slow enough that significant decay of the spin correlation occurs before recombination. The extent of this can be estimated from measurements of enhancement of fluorescence and is about 10% for solutions in cyclohexane[12], that is a measured T/S ratio of yields of 1, would correspond to an initial ratio of 0.82. Precise calculations are not possible at present, but there appears to be no inconsistency between the magnetic effect data and the measurements with pulse radiolysis, provided that recombination is the major source of excited states in alkane solutions

In striking contrast is the work of Lipsky *et al.*[13,14] who have measured the fluorescence yields of the alkanes themselves, avoiding complications produced by solutes. For bicyclohexyl, they estimate that T/S ≤ 0.25; this is an initial value since recombination in the alkanes is extremely fast (picoseconds)

The discrepancy can be explained by noting that processes A and B, in which an overall singlet spur produces two or more triplets, are both reversible; for example, in a two-pair cluster a triplet ion pair may recombine to a triplet molecule, which can exchange spins with the second electron as it returns to the neighbouring cation (being quenched in the process). Scavenging of electrons by a solute will allow more time for cation and triplet or two cations to separate, even though ion recombination may still occur in ≳1 ns. For solutions, the enhancement by the field varies considerably among the alkanes, this can hardly be due to process A; there seems to be a correlation with positive charge mobility—probably an effect of scavenging rate On this basis, one would expect larger overall yields of excited states in benzene etc, and this is found[13,14], process A, however, also contributes to this.

These results demonstrate the usefulness of the magnetic field effect for studying geminate ion recombination· measurements at long times are free from interference from energy transfer, which must be complete in a few nanoseconds; free ions only contribute to the background which is subtracted out.

This work was carried out at AERE, Harwell. I thank Dr W. G. Burns for providing equipment, the UKAEA, for support and the University of Sheffield for leave of absence.

Resistivity and the continental crust in southern Africa

DURING the last decade many deep electrical soundings have been made over the major Precambrian tectonic provinces of southern Africa[1,2]. The results (Van Zijl, submitted for publication) show that there are marked differences in the electrical properties between Archaean cratonic terrains (Kaapvaal and Rhodesian cratons) and mobile belts (Limpopo, Namaqua and Damara). The ages of the cratons are >2,600 Myr, whereas the dominant ages of the mobile belts are 2,700, 1,000 and 500 Myr, respectively[3]. In the discussion of crust here, the overburden or cover rocks of the various tectonic provinces have not been considered.

Cratonic terrains are characterised by a highly resistive zone extending from the surface down to a depth of 5–10 km depending on the locality. The average resistivity of this zone is about 100,000 Ω m with values varying between 30,000 and 500,000 Ω m. In some areas the highly resistive layer is overlain by a more conductive layer with an average resistivity of about 55,000 Ω m and a variable thickness.

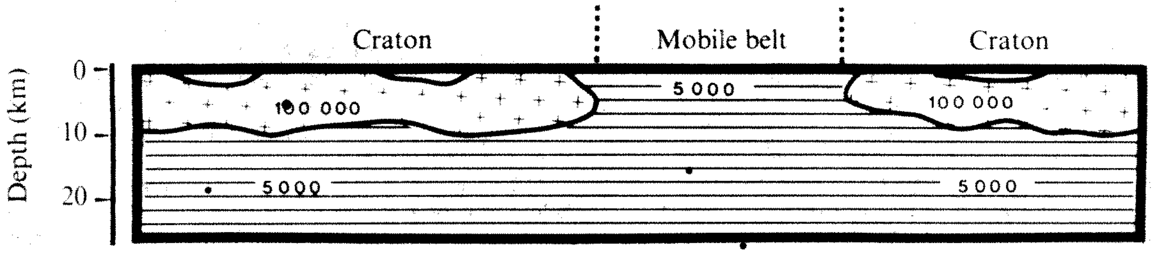
In contrast, the prominent highly resistive zone associated with the cratons is completely absent in the mobile belts. Instead, a thick moderately resistive zone with a resistivity ranging from 2,000 to 8,000 Ω m (average 5,000 Ω m) extending to a depth of 25–30 km is recognised. An important feature of this zone, deduced from closely spaced soundings, is that it continues laterally into the craton where it underlies the highly resistive layer. The electrical model is shown schematically in Fig. 1.

Correlation of the relevant electrical horizons with the results of geological investigations[1-10] shows the following relationships. First, the uppermost 5,000 Ω m layer observed in cratonic areas is due to the presence of metamorphic rocks of supercrustal origin. Second, the highly resistive zone in cratonic terrains is associated with vast amounts of granitoid material in the form of granitic intrusions, gneisses and migmatites. Third, the 5,000-Ω m layer of the mobile belts can be attributed to the presence of intensely deformed and highly metamorphosed rocks exhibiting features of upper amphibolite and granulite facies metamorphism. Fourth, the lower crust is metamorphic as deduced from the continuation of the 5,000-Ω m layer under the highly resistive layer associated with the cratons.

The view that the stable continental crust of cratonic areas is made up of a lower crust of high-grade metamorphic rocks underlying a more granitic upper crust which also contains remnants of supracrustal metamorphics, is not new. It was proposed, on geological grounds, by Wegmann[11] as early as 1935 and is supported by numerous later studies[12-18]. Geophysical arguments based particularly on heat flow[13], seismic[19] and gravity[20] investigations agree with this model. Basically, the lower crust is considered to consist of rocks which have largely been depleted of lighter granitic materials, volatiles and radioactive elements, leaving behind a refractory residuum. The metamorphic layer grades upwards into a zone in the upper crust consisting predominantly of granitic material occurring in the form of intrusions, gneisses and migmatites which were mainly mobilised from melts originating from the lower crust. It has often been noted that rocks of this zone both intrude and form the basement to supracrustal metamorphic rocks[4,14,21]. The extremely high resistivities associated with the granitoids indicate that the rocks are solid, strongly consolidated and largely unfractured.

The suggested correlation of the highly resistive layer with cratonic upper crust is significant as it provides a means of determining the extent of cratonic material even into adjoining mobile belts provided the grade of metamorphism remains low enough to prevent the migration of the granitoid material to higher tectonic levels[11]. Results to date indicate that the distribution of the ancient cratonic layer was indeed extensive and give the impression that this layer was broken up by the mobile belts studied. The Limpopo and Namaqua mobile belts, where a highly resistive cratonic material is bound on both sides of a core of moderately resistive highly metamorphosed rocks, are good examples. The view that the southern African mobile belts represent reworked and reconstituted cratonic crust[8,9,10,11,18] is thus supported by the electrical studies. Further evidence comes from complementary electrical information derived from the results of magnetometer array studies[21,22] which show that these mobile belts are not underlain by a highly conductive lithosphere as would be expected if they represented the traces of subduction zones involving oceanic crust. The mobile belts are thus regarded as being of ensialic origin, as suggested also by geological evidence[8,10].

Fig. 1 Schematic resistivity model of the Precambrian continental crust obtained from direct current Schlumberger electrical soundings. The average resistivities (Ω m) of the electrical horizons are shown. The highly resistive zones are associated with granitoid material (+) in cratonic terrains, whereas the more conductive zone is correlated with intensely deformed high-grade metamorphic rocks (—). The isolated synforms (white) overlying the granitoid material represent supracrustal metamorphics. Cover rocks are not shown.



The resistivity-derived model indicates that the floor of the mobile belts is formed by high-grade metamorphic rocks which are probably of deep crustal origin. In accordance with the views of Kröner[9] and Shackleton[18] it seems that the crust has become decratonised with time and is weakened, not stiffened, by events of deformation and metamorphism which have often been polycyclic.

The electrical model can be extended when account is taken of the absolute values of resistivity obtained from deep sounding results. From available temperature gradient estimates[23], it can safely be assumed that the temperature at a depth of 25–30 km is too low for conduction through minerals to be important[24] and that crustal rocks conduct electricity by virtue of interconnected cracks filled with water[24]. The space occupied by water can be calculated if the rock resistivity and the water resistivity are known[25]. While the latter parameter cannot be measured directly at great depths, it can be estimated by the extrapolation of water resistivities measured near the surface. From measurements on samples from boreholes and in mines (van Zijl, submitted for publication) a value of 1 Ω m has been assumed for water at depth. On this basis the porosity of the upper crustal cratonic layer is <0.5%, which substantiates its basically solid and unfractured nature as noted earlier. The mobile belts, on the other hand, have considerably larger porosities, varying from 3% near the surface to about 1% at a depth of 25 km, implying that these rocks are cracked and fractured and consequently weakened, not only in mobile belt areas but also in the lower crust under the cratons. Various studies have indicated that pore pressure is high during metamorphism and that a high degree of crack space is required[24,28]. These observations considered jointly with the intensely deformed nature of these rocks, may explain the origin of the cracks. The depth to which the connectivity of crack space continues will depend on the temperature at which permanent deformation of the rock minerals occurs. Experimental work[27] has shown that temperatures in excess of 500 °C are needed, which correspond to depths greater than 30 km in normal crustal situations. When viewed over geological periods, the interconnectivity of cracks, which come right up to the surface in mobile belts, implies hydrostatic pore pressure[28] and a decrease of porosity with depth[28]. This supposition is supported by the resistivity results over mobile belts, as noted earlier. The origin for the water in the crust may thus be meteoric[29]. The several-fold increase of the porosity at the boundary of cratonic layer and the underlying metamorphic zone may account for the low velocity layer found at this depth in the Canadian Shield[30], a region geologically similar to the areas studied in southern Africa.

The suggestion that free water is available at all levels in the crust has many implications regarding physical processes and geochemical effects. The variation of heat flux and the nature of the crust–mantle boundary are only two examples.

Thermal gradients[31] and heat flow estimates (A. E. Carte, personal communication) from mobile belts appear to be anomalously high when compared to cratonic terrains, especially when the lower heat production of highly metamorphosed rocks[13] is taken into account. This paradox may possibly be explained by the transport of heat by the preferential upward movement of water through the cracked metamorphic zone and its concentration in mobile belts. Regarding the crust–mantle transition zone, electrical sounding results sometimes show the presence of a conductive layer at this depth which is interpreted at present as being due to hydration processes of mantle rock (van Zijl *et al.*, in preparation).

It is clear that electrical resistivity is intimately associated with both the nature and the structure of the continental crust; its usefulness as a tool in crustal investigation critically depends on the quality of the data obtained from electrical investigations.

Age and position of the Ellsworth Mountains crustal fragment, Antarctica

The present geographical position of the Ellsworth Mountains is geologically anomalous on account of their stratigraphy, which does not relate to western Antarctica, their structural trend, approximately perpendicular to the trend in adjacent regions, and their relief, the greatest, and possibly the youngest, in Antarctica. These factors suggest that the Ellsworth Mountains are not in their original position but have moved, probably during the Cainozoic.

During a radio-echo ice-depth-sounding flight on January 22, 1975 from the remote American 'Siple' station in inland Antarctica, a British Antarctic Survey aircraft landed beside two small nunataks at the edge of the Ronne Ice Shelf at 77°02′S, 78°20′W (Fig. 1). In 1947, Ronne[1] sighted a nunatak at 77°40′S, 79°00′W which he named Mount Haag. As we found no other nunataks within 180 km, these are considered to be Mount Haag, now renamed Haag Nunataks.

Under the direction of Dr C. W. M. Swithinbank, seven specimens of the *in situ* rock types were collected comprising four granodiorite–gneisses, one hornblende schist, one quartzo-feldspathic gneiss and one acid vein cutting gneiss. All but one of the rocks show acid veining to some extent.

The granodiorite–gneisses generally have a strong foliation marked by biotite (<10%) which is frequently altered to chlorite and associated with hornblende (<3%). Quartz crystals are mostly strained, often fractured and may occur as single crysals or in a mosaic. Oligo-andesine, usually heavily sericitised, is predominant, and potash feldspar is present mainly as microperthite of a string or bead type, but microcline with characteristic twinning also occurs.

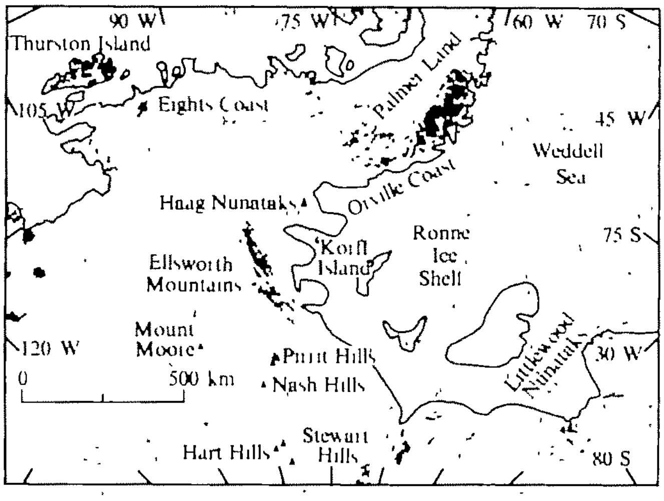

Fig. 1 Map of the Ronne Ice Shelf and its environs; areas of exposed rock are shown in black

Potash feldspars rarely show any alteration, and clear untwinned feldspars are probably cryptoperthite. Accessory minerals include pistacite, sphene, allanite and ore minerals.

The hornblende schist has a granoblastic texture and comprises about 29% green hornblende, 39% andesine with quartz, biotite, accessory sphene and some ore. Acid veinlets and augen in the schist are much richer in quartz and contain some potash feldspar whereas hornblende is a minor constituent. The quartzo-feldspathic gneiss consists of microcline augen, quartz, perthite, plagioclase and biotite. The specimen of an acid vein in gneiss is essentially similar in the vein part to the quartzo-feldspathic gneiss and to the grandodiorite–gneisses in the gneissic part.

These rocks seem to have been regionally metamorphosed to amphibolite facies and suffered synorogenic invasion by acid veins. No observations of field relationships could be made but colour photographs of the outcrop suggest that some of the rocks may be migmatites.

This suite of rocks is typical of many regional metamorphic terrains of Antarctica but the nearest known outcrops of similar rocks are along the Eights Coast and in the eastern part of Thurston Island[2] or in the coastal regions of northern Palmer Land[3] 'Granites intrusive into gneisses' were reported, however, at 81°53′S, 69°20′W by the 'Ellsworth' station–'Byrd' station traverse party[4]. The nearest outcrops inland of the Orville Coast[5] and in the Ellsworth Mountains[6] comprise sedimentary rocks, those in the Nash and Pirrit Hills contain granitic intrusions, and Mount Moore and the Stewart Hills consist of phyllite and schist[7]. Behrendt[8] reported a nunatak to the west of 'Korff Island' but this is now considered to be an ice fall (C. W. M. Swithinbank, personal communication).

K–Ar determinations on two gneisses from Haag Nunataks have yielded the results shown in Table 1.

The concordant dates obtained from separates of hornblende and co-existing biotite provide a minimum age for the last major regional metamorphism affecting the gneisses. The lower apparent ages obtained from the potash feldspars and plagioclase are due to argon loss from these less retentive minerals, and are not necessarily geologically significant. It is interesting that a date of 1,044 Myr (ref. 9) has been obtained from rhyolites in the Littlewood Nunataks and may reflect some association in time and space with the gneisses from Haag Nunataks.

Schopf[10] suggested that the Ellsworth Mountains lie on a fragment of continental crust which has moved to its present position from the north-east. Assuming Haag Nunataks are an up-faulted slice of the metamorphic basement underlying the Ellsworth Mountains, these dates provide additional evidence to suggest that the Ellsworth Mountains area was originally along the western margin of the Antarctic plate. Apart from a deep subglacial trough between the Ellsworth Mountains and the Orville Coast[11] which may continue eastward to the north of Haag Nunataks, there are insufficient data to delimit the margins of this fragment of continental crust until the bedrock topography of the Weddell Sea and its environs is known. The structure and stratigraphy of the Ellsworth Mountains[11] and the ages from Haag Nunataks suggest an original position for this fragment of continental crust westward of the Littlewood Nunataks (where there is a bathymetric depression), but an accurate palaeogeographical reconstruction of this region must await palaeomagnetic data from the Weddell Sea floor.

Table 1 Analytical data

Sample no.	Material analysed	% K	Vol. rad. ^{40}Ar (nl g^{-1})	Age (Myr)
E.4690.1	Hornblende	1.04	55.79	1,018±28
	Biotite	6.39	332 3	991±22
	K-feldspar	10.4	381.5	745±18
	Plagioclase	0.553	16 45	628±18
E.4690.2	Hornblende	1.01	55.30	1,031±14
	Biotite	6.79	358.3	1,002±24
	K-feldspar	9.99	356.2	731±18
	Plagioclase	0.676	18.86	595±16

Ages have been calculated with $\lambda_\beta = 4.72\times10^{-10}$ yr^{-1}, $\lambda_e = 0.584\times10^{-10}$ yr^{-1} and ^{40}K/K = 0.0119 at %.

Errors are quoted at the 2σ level and take into account uncertainties in the mass spectrometer ratio measurements, spike calibration, atmospheric argon correction and potassium determinations.

Argon concentration was determined by standard isotope dilution techniques and potassium was determined in quadruplicate by flame photometry.

We thank Dr C. W. M. Swithinbank for the opportunity to study these specimens. The flight to Haag Nunatak was made possible through the provision of aviation fuel and accommodation by the NSF at 'Siple' station.

Geochronological evidence of Hercynian activity in Newfoundland

A RECONSTRUCTION of the continental blocks for the central and North Atlantic has led to the widespread acceptance of the continuity of the Palaeozoic orogenic belts on both sides of the Atlantic. A reconstruction of the land masses during the Carboniferous and Permian shows the Variscan Belt of Europe, the Mauritanides of Morocco, and the

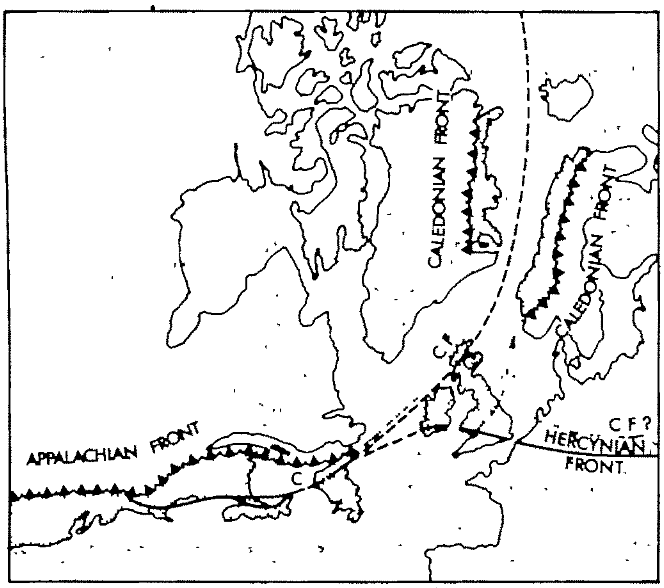

Fig. 1 Reconstruction of continental blocks around the North Atlantic during the Permian (after Holmes[3]) C. F., Caledonian Front of northern Scotland; G, Great Glen Fault; C, Cabot Fault

Southern Appalachians as being continuous[1]. Although the Hercynian Front has now been recognised in New Brunswick[2] the situation in Newfoundland is unclear We suggest, on the basis of the geochemical data outlined in Table 1, that the continuation of these belts can be interpolated between New Brunswick and south-west England to include at least the Central Mobile Belt and the Avalon Zone of Newfoundland We find the earlier correlation by Holmes[3] particularly attractive in view of our new isotopic data, a correlation which extends the Hercynian Front westwars from south-west England and Wales into Canada, where it passes along the Cabot Fault into the New Brunswick seaboard and the Bay of Fundy (Fig. 1) Cherkis *et al*[4] link the Charlie Gibbs Fracture Zone to the Hercynian Front on both the European and North American continents, and have recently offered new evidence for the emergence of the front in Newfoundland[5]. The intersection of the Charlie Gibbs Fracture Zone and the continental shelf of Newfoundland lies about 100 km east of the Cabot Fault, so that their delineation of the front lies further to the south than the one outlined here

The four granites listed in Table 1 and shown in Fig 2 record either intrusive or deformational events of Carboniferous age. Three of these granites are emplaced into the crystalline margins of the Central Mobile Belt, while the St Lawrence granite is intrusive into Palaeozoic and Late Precambrian sedimentary and volcanic sequences of the Avalon Zone. The St Lawrence granite, a non-foliated, high-level, peralkaline body associated with fluorite mineralisation, intrudes a zone of weakness marked by a series of north–south trending folds, north–east trending synclines, and high-angle thrusts that run parallel to the fold axes[6]. The remainder of the granites are either sheared or cataclastically affected by regional deformation. The Lockers Bay granite, a megacrystic microcline variety, is intimately associated with the Dover Fault, a major tectonic discontinuity that separates the northern part of the Central Mobile Belt from the Avalon Zone. This granite was considered to be Hadrynian in age, or older[7]. To the north, in the Burlington Peninsula area, the regional deformation which post-dates the intrusion of the LaScie intrusive complex and the Cape Brulé porphyry has been attributed to either pre-Ordovician[8,9] or post-Lower Ordovician–Devonian movements[10]. At least two phases of deformation have affected the LaScie complex; using some of the geochronological evidence presented here, DeGrace *et al*[11] concluded they "are probably both Hercynian deformations"

Widespread basement reactivation in Europe during late Carboniferous times (Westphalian–Stephanian) produced many of the granitic masses of the Bohemian Massif, the Iberian Peninsula, Morocco, the Schwarzwald and the Massif Central. As a consequence of partial melting of a thickened continental crust (brought about by continent–continent collision of the northern and southern European plates) these granites were enriched in potassium relative to their more sodic counterparts formed during the Caledonian Orogeny[12]. Similarly, the granites listed in Table 1 seem to be quite different to granites of Devonian age that we have dated from Newfoundland. The marked contrast of the initial ratios shown in Table 1 to the lower ratios (0.704–0.709) for many of the Acadian granites is entirely consistent with derivation of the younger granites by partial melting of continental crust.

Variations in age, deformation and metamorphism along the length of the Caledonian–Appalachian–Hercynian

Table 1 Whole-rock Rb–Sr isochron data*

Locality	Petrographic and geochemical notes	Apparent age (Myr)	Initial $^{87}Sr/^{86}Sr$ ratio	No. of points
LaScie Intrusive Complex	Fine- to medium-grained alkali granite; mainly quartz, orthoclase; rare plagioclase, amphibole and opaques; traces of epidote and carbonate—evidence for cataclasis	315±25	0.715±0.012	5
Cape Brulé porphyry	Feldspar and embayed quartz phenocrysts set in fine-grained groundmass; alteration products, sericite, chlorite; traces of calcite, fluorite; some evidence for cataclasis	325±14	0.7145±0.0018	5
Lockers Bay granite	Megacrystic microcline, biotite granite; strongly schistose —microcline phenocrysts some flattened; granulation of quartz and feldspars; epidote common	300±18	0.7146±0.0013	6
St Lawrence granite	Red to pink, medium- to fine-grained; mainly quartz, orthoclase, albite, with minor riebeckite, aegerine, biotite, fluorite, magnetite and haematite, perthitic and granophyric textures common	315±10	0.722±0.005	4

orogen have been attributed to either irregularities in the geometry of the colliding continental plate margins[11], or to an oblique collision[14]. The result, in both cases, is the formation of numerous small plates, wedges and splinters of continental crust, usually bounded by transcurrent faults. After the Hercynian orogeny the division of Newfoundland into a series of independent fault-bounded blocks could account for the distribution and origin of many of the geological features that are now observed in the Central Mobile Belt High-angle faults, many of them transcurrent, abound in the central part of Newfoundland, and are especially numerous close to the boundary between the Central Mobile Belt and the Lomond Zone. Some time after collision, crustal thickening along with transcurrent faulting led to partial melting of the continental crust which produced Mid-Carboniferous magmatism and mineralisation Deformed Carboniferous strata contained in a narrow, elongate, fault-bounded trough which trends from Cape Anguille in the south-west to White Bay in the north-east gives some stratigraphic significance to the interpretation of our isotopic data. The unconformable relationship of the Deer Lake Group with the basement and the Anguille beds in north-central Newfoundland testify to early and late Mississippian deformation[15].

Both the stratigraphic and isotopic evidence support the model of Dewey and Burke[1], which includes southern Europe colliding with Europe/North America in Mid-Carboniferous times The later post-Stephanian (Maritime or Alleghenian) disturbance further to the south coincided with Africa south of the South Atlas Fault sliding westward to collide with North America[16].

For convenience, and to follow earlier workers, we use the term 'Hercynian Front' here, even though its meaning is poorly defined

Slow recolonisation of deep-sea sediment

USING the submarine ALVIN, experiments on deep-sea benthic communities have been designed to follow the recolonisation of defaunated deep-sea sediments and to provide estimates of growth rates and time to maturity in individual species Small brood size and the high proportion of adults in a number of deep-sea benthic taxa suggest relatively low rates of recruitment, growth and mortality in the deep sea[1]. Large individuals (8 4 mm) of the deep-sea bivalve, *Tindaria callistiformis*, have been estimated to be at least 100 yr old[2]. Measurements of microbial activity and community respiration indicate rates one to three orders of magnitude lower than in shallow water[3,4]. In contrast with the view that there is a general slowing of life processes, the first *in situ* deep-sea measurements on molluscan borers in wood panels have indicated rapid rates of recruitment, growth and maturation. Wood is, however, an ephemeral resource and its occurrence in the deep sea is unpredictable, while the majority of deep-sea habitats are thought to be highly predictable, therefore favouring less opportunistic life histories.

Studying community succession in defaunated sediments gives hope of predicting the rate of recovery of deep-sea communities following a disturbance and assessing the normal role of disturbance in structuring these remarkably diverse communities. The *in situ* placement of defaunated sediments in benthic studies is similar to the use of fouling panels or artificial three-dimensional habitats

In September 1972, the research submersible ALVIN placed boxes (50×50×10 cm) of azoic sediment at a depth of 1760 m at the first Woods Hole Oceanographic Institution Permanent Bottom Station (PBS 1) (39°46′N, 70°40′W). The sediment was previously collected in the same area at approximately the same depth with an anchor dredge. It

was kept at room temperature for at least 2 weeks, then frozen at −30 °C for at least 1 week, and then thawed. One box was retrieved in 1974 after it had been on the bottom for 26 months and the second box was cored *in situ*, also after 26 months, with eight 35-cm^2 tubular cores. Similar tubular cores were also used in 1972 and 1973 to obtain a total of 25 control cores from surrounding sediments at PBS 1. A third box was placed at PBS 1 in July 1975 and retrieved after 2 months. Another box of the same size, containing similarly treated Buzzards Bay mud was placed on the bottom at a depth of 10 m in Buzzards Bay in July 1971 and was sampled after 2 months with six 35-cm^2 cores. All macrofaunal animals (excluding nematodes, podocopid ostracods and copepods) retained by 0.297-mm screens were used in the analysis. Subsamples from the experimental boxes indicated no spatial patchiness as was also true in the control cores from the sea floor even though the control cores were taken at several different times.

Experimental boxes showed an order of magnitude fewer individuals and species than surrounding sediments (Table 1). The 2-month box (PBS-1, experiment 1) was dominated by larvae of the wood-boring *Xylophaga* sp. and the loricate larvae of *Priapulus atlantisi*. The abundance of *Xylophaga* sp. probably results from the proximity of wood panels placed on the same dive. All individuals of the other taxa were post-larvae or juveniles except for two adult ectoparasitic snails (*Eulima stenostoma*) which may have crawled in or been carried in by an echinoderm passing over the box. The 26-month boxes (PBS 1, experiments 2a and 2b) were dominated by juveniles of four species and adults of an as yet undescribed capitellid polychaete of the *Capitella* species complex (Table 2)[6]. The finding of a species in the *Capitella* group in the deep sea is of considerable interest, since species of this group have been recognized as indicators of disturbed conditions in shallow-water environments[7]. Only a few individuals of the *Capitella* group have previously been found in extensive collections from the deep Atlantic[8]. Hartman found large numbers of worms of similar description from collections in the vicinity of freshwater aquifers off California at depths up to 500 m (ref. 9). Polychaetes, *Glycera mimica* and *Neopodarke woodsholea*, and a bivalve, *Nucula cancellata*, were among the five numerically dominant species. An ectoparasitic gnathiid isopod was the most abundant species in the box even though it is relatively rare in surrounding sediments. Of the 141 individuals in the box sampled completely, only 18 adults were found: 16 individuals of *Capitella* sp., a single individual of the capitellid polychaete genus, *Heteromastus*, and a single adult tunicate, *Polycarpa delta*. The smaller area sampled from the box cored *in situ* showed a similar species composition.

Three of the five most abundant species in the PBS 1 26-month boxes are predators or ectoparasites and 64% of the polychaetes are in groups known to move about actively as adults; that is, most of the species settling in the boxes as larvae are relatively motile forms.

The results presented demonstrate a tremendous difference between rates of colonisation in shallow-water at a depth of 10 m and these rates in the deep sea. Comparison of two boxes sampled on the bottom (shallow-water and deep-sea) after 2 months indicates two orders of magnitude lower density in the deep-sea box. The 41 larval and post-larval individuals and two adults in the deep-sea box belong to 14 species. The shallow-water Buzzards Bay box contains thousands of individuals ranging from post-larvae to adults of at least 47 species. The difference is even more striking if the study on similar boxes placed in an intertidal mud flat is used as a basis for comparison[7]. The experiments in the intertidal zone demonstrate an even faster response with high densities of opportunistic species settling as larvae in the boxes and many growing to adults within a month. In the deep sea the densities do not rapidly increase to saturation levels. Indeed, more recent results from greater depths suggest even lower rates of colonisation. We cannot discount the possibility that densities are kept low by predation[10,11], but if this is so, the predation seems to be continuous, in that it is observed in both 2-month and 2-yr boxes, and does not result in patchy distribution within the boxes.

These results indicate that disturbance resulting in severe reduction of deep-sea fauna may be a long-lasting source of spatial heterogeneity (on the same scale as the disturbance) with the effects of disturbance apparent for at least 2 yr and probably much longer. Effects of disturbances 100 cm^2 or larger have not been observed in studies of patchiness in the deep sea, but the life and death of individual organisms can create local heterogeneity[12]. Life processes as reflected in rates of colonisation and growth are remarkably slow in the deep sea. Thus, small-scale spatial and temporal mosaics resulting from disturbances on the scale of individual organisms may have a major role in structuring highly diverse deep-sea communities.

I thank Linda M. Cole for technical assistance and Howard L. Sanders for advice. The ALVIN group at Woods Hole helped in many ways. The research was supported by the NSF.

5-^{125}I-iododeoxyuridine as prototype for radionuclide therapy with Auger emitters

MANY of the physical and biological requirements for treating cancer with internally emitting radionuclides are met by 5-^{125}I-iododeoxyuridine (^{125}IUdR). The decay of ^{125}I is associated with a highly localised deposition of energy[1]. Cascades of very low energy and thus densely ionising Auger electrons are released. In addition, a charge transfer reaction takes place leaving the resultant tellurium nucleus with a transient mean net charge of +9 (ref. 2). These unique physical characteristics can be used for cell destruction by labelling DNA with ^{125}IUdR, a thymidine analogue. The marked radiotoxicity of ^{125}I incorporated into DNA as ^{125}IUdR has been demonstrated by lethality, mutations and DNA strand breaks in bacteria and bacteriophage[1–7], by lethality and chromosome aberrations in mammalian cells cultured *in vitro*[8–10], and by diminished survival of prelabelled tumour cells assayed *in vivo*[11]. The intranuclear location is of major importance: ^{125}I located extracellularly[9] or bound to cell membranes is much less toxic (unpublished work of R. L Warters and K. G. Hofer) These findings suggested that ^{125}IUdR might have significant anti-neoplastic activity. We tested this hypothesis in a murine ascites tumour model[12,13]. In a pilot study using therapeutic doses of ^{125}IUdR, the agent substantially augmented the median and absolute survival of treated animals. The critical factors affecting treatment of a 1-d-old ascites tumour model with ^{125}IUdR are detailed here.

The tumour used in these experiments arose spontaneously in the ovary of a C3H mouse[14] and has been maintained as an ascites tumour by serial intraperitoneal (i.p.) transplantation in female C3HeB/FeJ mice (Jackson Laboratory) Median survival of untreated animals was determined after i.p. challenge with various tumour cell inocula (Fig. 1). The non-linearity observed at low tumour cell inocula ($<10^3$ cells) suggests that host defenses may be effective in these circumstances The relatively long survival of tumour-bearing mice facilitates quantitative evaluation of tumour cell killing after treatment with ^{125}IUdR and Fig. 1 can be used to calculate a cellular survival fraction. For example, the median survival of mice given 10^7 cells is 19 d; if treatment prolongs it to 29 d, the treated animals died as though they had been given 10^3 cells. This represents a survival fraction of 10^{-4}. The calculation assumes that treatment with ^{125}IUdR does not alter the pathogenicity of tumour cells destined to survive, and the absence of a shoulder on the *in vitro* survival curve of cells exposed to ^{125}IUdR supports this assumption[8,10].

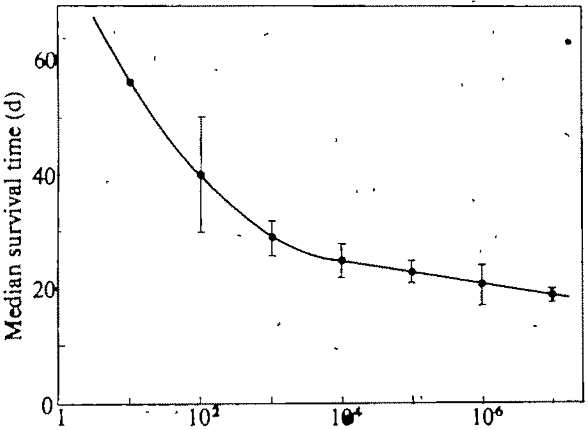

Fig. 1 Median survival ± standard deviation of untreated mice after i.p. injection of various tumour cell inocula. The median survival after injection of 10 cells represents the pooling of data from 14 experiments, in six of which fewer than half the animals died when followed for 150 d.

Parameters of the cell cycle were determined for 1-d-old ascites tumour cells by the percentage labelled mitoses method[15] (Fig. 2). From computer analysis of the data[16], the total cell cycle time was calculated to be 14.3 h, DNA synthetic time 5.8 h, G_1 6.3 h, G_2 1.7 h, and mitosis 0.5 h. Because ^{125}IUdR is incorporated into DNA only during synthesis, it is important to match fractionation to the cell cycle. As the growth fraction for 1-d-old ascites cells approaches unity, all tumour cells can theoretically be labelled by appropriate schema Optimal cell killing will be achieved by increasing the overall treatment time to cover several cell cycles and, in the absence of continuous infusion, maintaining an interval between treatments that is less than the DNA synthetic time.

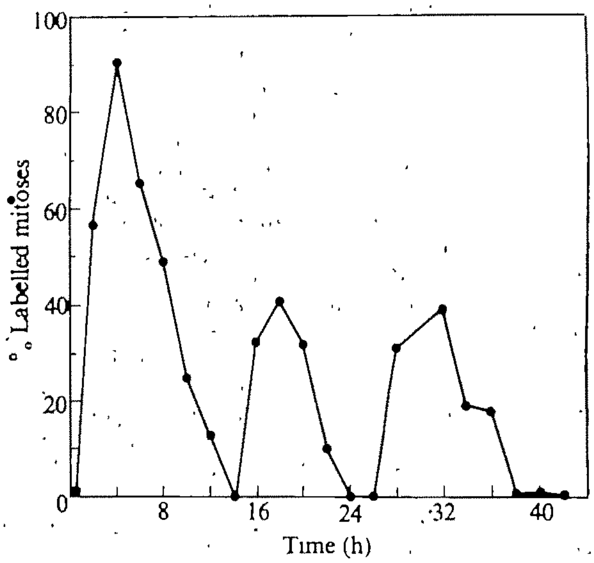

Fig. 2 Percentage labelled mitoses as a function of time after a single injection of 10 μCi ^{3}H-thymidine administered 1 d after inoculation of 10^6 tumour cells. Mice were killed at 2-h intervals; tumour cells were extracted from the peritoneal cavity by flushing, washed, fixed in methanol–acetic acid (3:1), and dropped on to slides. Autoradiography was performed with NTB-2 nuclear track emulsion (Eastman Kodak).

All experiments involved carrier-free ^{125}IUdR (New England Nuclear) administered i.p starting 24 h after inoculation of 10^6 tumour cells. The overall treatment time was 12–24 h with the interval between treatments being 4 h Because ^{125}IUdR is dehalogenated rapidly *in vivo*[17], potassium iodide was added to animal drinking water to block thyroid uptake of released radionuclide. Experiments were followed for at least 100 d No gross acute or chronic toxicity was observed in treated animals and all deaths were associated with ascites formation.

Optimal conditions for ^{125}IUdR therapy were achieved by studying the effect of sequential treatments on tumour cell survival and establishing a dose-response relationship. In Fig 3, tumour cell survival is plotted as a function of the number of treatments administered, the dose per treatment being constant The effect of using four to seven sequential treatments is to extend the overall treatment time from 12 to 24 h, an increase approximating one cell cycle time. Because ascites cells are asynchronous, increasing the number of treatments and hence the overall treatment time would be expected to reduce further the survival fraction. The incremental reduction in survival fraction decreases with each successive treatment because fewer and fewer cells remain viable to incorporate ^{125}IUdR.

Tumour cell survival as a function of the dose of ^{125}IUdR per treatment is shown in Fig 4 Seven treatments were

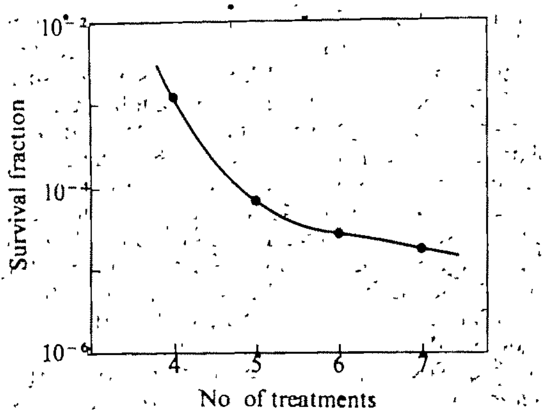

Fig. 3 Tumour cell survival as a function of sequential treatments with ^{125}IUdR (25 μCi every 4 h).

administered at 4 h intervals beginning 24 h after tumour cell inoculation. There is a steep and marked reduction in survival fraction at doses up to 15 μCi per treatment with a plateau observed at higher doses.

Both Figs 3 and 4 are complementary in that seven treatments of 25 μCi ^{125}IUdR result in a survival fraction of about 10^{-5}. Considering that the challenge dose was 10^{6} cells, these data suggest that there is a very small fraction of tumour cells that are non-cycling or have long generation times. Increasing the number of treatments and overall treatment time or the use of continuous infusion might have killed these few remaining cells but perhaps at the risk of damaging critical normal tissue cell renewal systems.

In other studies[12,13], we showed that Na^{125}I, ^{131}IUdR and Na^{131}I had no anti-neoplastic activity when administered in similar doses and using a similar regimen to that used for ^{125}IUdR. The decay of ^{131}I is by β-minus emission and is not associated with any significant yield of Auger electrons or a charge transfer reaction. No anti-neoplastic activity was observed with non-radioactive IUdR administered in amounts comparable with ^{125}IUdR. That the anti-neoplastic activity of ^{125} IUdR is primarily due to the radiotoxicity of ^{125}I incorporated into DNA is further supported by the failure to observe X-ray sensitisation in tissue culture at concentrations of IUdR that are toxic when used as ^{125}IUdR[8].

We conclude that ^{125}IUdR has marked anti-neoplastic activity and provides the basis for a new approach to the treatment of cancer. We appreciate that any early ascites tumour model is a propitious system in which to test the efficacy of cell cycle active agents. In particular, a favourable therapeutic ratio results from the direct access of drug to tumour cells in the peritoneal cavity before ^{125}IUdR enters the general circulation where dehalogenation occurs; such dehalogenation in turn protects normal cell renewal systems. Further work will be necessary to determine the efficacy of ^{125}IUdR in solid tumours where the growth fraction is considerably less than unity and drug access is less direct. Nevertheless, the exquisite radiotoxicity of ^{125}I incorporated into DNA represents a challenge to synthesise and evaluate other labelled agents with high nuclear affinity.

We thank Mr Gerald Vattuone and Dr Mortimer L. Mendelsohn for analysis of cell cycle data and Mr Edward C. Williams for technical assistance. This work was supported by grants from the NCI and ERDA.

First North American record of the extinct panda *Parailurus*

THE living pandas are restricted to the mountains of south-eastern Asia where both the giant panda (*Aeluropoda*) and the lesser panda (*Ailurus*) occur. They overlap in geographical range only in Szechuan, China, and there they are separated altitudinally, with the lesser panda favouring higher elevations[1]. Pleistocene records extend the range of the giant panda into Burma and eastern China, but the lesser panda has apparently not had a significantly wider range during the Quaternary[2]. Considerable controversy surrounds the phylogenetic relationships of both genera as they represent some of the most derived of terrestrial Carnivora. Recent marshalling of anatomical evidence on the giant panda has demonstrated its fundamental affinity with other members of the Ursidae[3]. The position of the lesser panda is equivocal although it is usually assigned to the Procyonidae. Procyonids are widely thought to be restricted to the New World, but recent work on various Oligocene and early Miocene forms in Europe[4] and North America[5] indicate that the procyonids had a Holarctic distribution at that time. Regardless of its broader phylogenetic affinity, the presence of medial and late Miocene relatives of the lesser panda in Pakistan and western Europe (*Sivanasua* Pilgrim, 1931 = *Schlossericyon* Crusafont, 1959)[6] and their absence in the New World makes an Old World origin for this group highly likely. Thus the discovery of a single tooth in North America almost identical to European specimens of the extinct lesser panda *Parailurus* is unexpected, and must be explained by immigration from Asia.

It has long been known that Eurasiatic mammalian immigrants had an increasingly important role in the late Cainozoic fauna of North America, and in Quaternary time such allochthonous groups came to dominate the large mammal fauna of the New World[7]. Recent study[8-10] of Pliocene (Blancan) assemblages of the north-western United States has added new taxa to the growing list of forms first appearing in the New World during that interval. The discovery of remains of the extinct panda *Parailurus* Schlosser, 1899, in the Taunton Local Fauna of the Ringold Formation of Washington adds another element to this list. It is interesting that the Ringold and correlated Glenns Ferry formations (see below) contain several mammals representative of the oriental temperate woodland fauna that appear simultaneously in Europe in the Pliocene. In the New World these immigrants include the grison *Trigonictis*[8] (close to *Enhydrictis*), the bear *Ursus* (*U. abstrusus*[8] close to *U. boeckhi*), true otters (Lutrinae, represented by *Satherium*[8] in North America) and primitive Cervidae with antlers of the 'three-point plan' of Geist[9] (*Bretzia*[10] with palmate antlers similar to Eurasiatic late Miocene *Cervavitus*). The recent discovery of the petauristine squirrel *Cryptopterus* in the Blancan of Florida[11] adds another oriental element to the Pliocene fauna of North America. In European sites yielding *Parailurus*, similar associations of mammals occur in the late Pliocene at localities of late Ruscinian (Csarnotian) age in England (Red Crag)[12], West Germany (Wölfersheim)[13] and Rumania (Barót-Köpec)[14] and those of early Villafranchian age in Italy (Arondelli[15] of the Villafranchian stratotype area), and Czechoslovakia (Hajnàcka)[16,17]. The known Pliocene faunas of Asia are of different character and seem to represent a steppe or savanna (mixed grassland and forest) biotope, that, judging from available records[18], extended northwards to the latitude of Lake Baikal. There is evidence for a Pliocene temperate forest biome that ranged at even higher latitudes across Holarctica[19], and thus a pathway is present to permit the widespread occurrence of the fauna associated with such environments.

The Taunton Local Fauna was obtained from flat-lying fluviatile deposits resembling those of the stratotype Ringold Formation at White Bluffs on the Columbia River, 24 km to the south. The higher topographic position for the Taunton site suggests that it may equate with the uppermost part of the type Ringold sequence, above the occurrence of the White Bluffs Local Fauna[10]. Fish remains are the most abundant fossils at the Taunton Site and most of these pertain to a perch (*Archoplites taylori*) and a catfish (*Ictalurus vespertinus*), both of which are common in the Glenns Ferry and type Ringold formations. Mammals are mostly known from isolated teeth. Most common are *Equus* (*Dolichohippus*) *simplicidens*, two species of the rabbit *Hypolagus*, and an antilocaprid similar in size to the living pronghorn. On the whole, the Taunton Local Fauna is similar to both the White Bluffs Local Fauna and the Hagerman Fauna. But the following differences are apparent when comparisons are made with the former: the presence of two species of *Hypolagus*, neither being the White Bluffs form; the presence of *Pliopotamys* cf. *minor* and the giant beaver *Procastoroides;* the presence of the badger *Taxidea;* the presence of *Canis lepophagus* rather than *C. davisi;* the absence of a more primitive *Equus* with short protocones; the rarity of cervids and the peccary *Platygonus*, and the presence of abundant antilocaprid remains. Some of these differences may be due to ecological bias. The stream which deposited the sediments containing the Taunton Local Fauna seems to have been a relatively minor tributary. Riparian forests that probably broadly lined the major stream at White Bluffs may also have extended as a narrow belt into the Taunton tributary with savannah or open grassland nearby. This situation would explain the large percentage of rabbits, horses and antilocaprids as well as the presence of a smaller number of presumably forest animals at Taunton. Other differences can be construed as indicating closer temporal equivalence of the Taunton Local Fauna with the younger Hagerman than with the older White Bluffs Local Fauna. Such faunas are attributed to the earliest half of the Blancan Mammal Age of North America.

Biochronologically the occurrence of a species of *Parailurus* close to *P. anglicus* in North America serves to reinforce the correlation of the early Blancan faunas of which it is a part with those of Late Ruscinian and early Villafranchian Age in Europe[20]. Radiometric calibration of these biochronological units in North America and Europe confirms this biological correlation: the Taunton Local Fauna is no younger than the Hagerman Fauna, the latter dated at 3.2–3.5 Myr (ref. 21). The early Villafranchian Etouaires Local Fauna of the Perrier Plateau, Auvergne, is just above a volcanic ash dated 3.4 Myr and is overlain by pumice dated 3.3 Myr (ref. 22). If the Vialette Local Fauna from the Auvergne is taken as Late Ruscinian in age and has a minimum date of 3.8 Myr (ref. 20) (established by the date on the overlying basalt), the Ruscinian–Villafranchian boundary would fall between 3.4 and 3.8 Myr. In round figures the known biochron of *Parailurus* would fall across this boundary probably within the interval 3.0–4.0 Myr.

The North American *Parailurus* is represented by a highly diagnostic upper right first molar (Los Angeles County Museum 10808) collected by George F. Beck of Yakima, Washington from fluviatile gravels and cross-bedded sand (284.0 m above sealevel) that in turn overlie laminated chalky clay and are overlain by late Quaternary loess, 0.8 km east of Taunton station (LACM Locality 6408, 46 41′N latitude, 119°21′W longtitude), Adams County, Washington. This tooth is longer anteroposteriorly than it

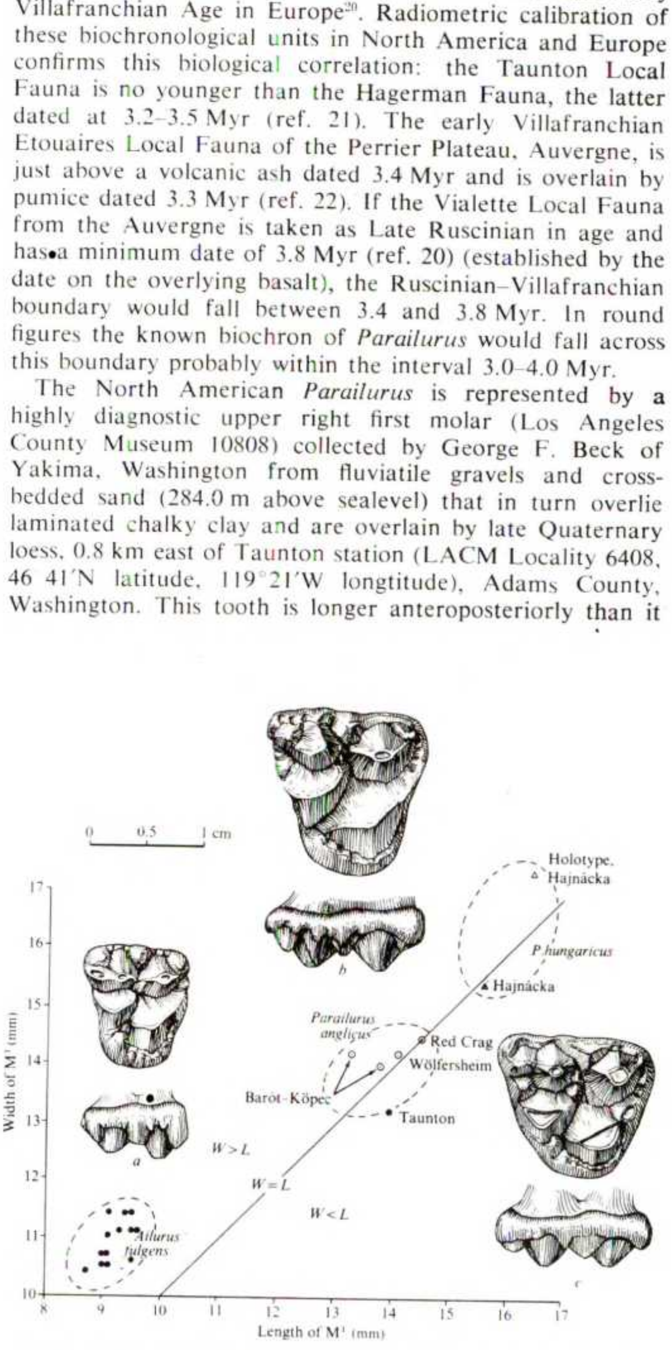

Fig. 1 Occlusal and labial views of right first upper molars of living and fossil lesser pandas, drawn to the same scale. *a*, *Ailurus fulgens* AMNH 80164, Recent, zoo; *b*, *Parailurus* cf. *anglicus*, Senckenberg Mus. Wö 21, Pliocene, W. Germany; *c*, *Parailurus* sp., LACM 10808, Pliocene, Washington. Regression plot of length × width of the first upper molar.

is wide transversely (length 14.0 mm, width 13.2 mm) in contrast to European *Parailurus* in which the teeth are more nearly equidimensional or slightly wider than long. *Ailurus fulgens*, the living lesser panda, has smaller first molars that are markedly wider than long. The complex crown pattern of the Taunton form agrees in most details with those known for *Parailurus*, as shown in Fig. 1, where LACM 10808 is compared with the specimen from Wolfersheim (Senckenberg Museum Wö 21), West Germany. The labial cingulum is weaker than in other *Parailurus* particularly that behind the mesostyle where stylar cusps form a more complex structure in *P. anglicus* and *P. hungaricus*. Likewise, the lingual cingulum is weaker in the American form giving the tooth a more triangular occlusal outline. But too few specimens of any population of *Parailurus* are known from which to judge the significance of the small differences that can be observed. The sample of *Ailurus fulgens* available (14 individuals from the American Museum of Natural History collection, three wild, the remainder zoo animals) shows a rather remarkable uniformity in size and morphology for an arctoid carnivore, suggesting that the difference in size between *P. anglicus* and *P. hungaricus* is probably significant biologically and that the morphological differences noted between the American and European forms are also significant. At present it seems most prudent to designate the American panda simply *Parailurus* sp., noting that among the described European species it compares most favourably with the late Ruscinian *P. anglicus*.

We thank Drs D. P. Whistler and L. Barnes for permission to describe the Taunton panda tooth; Dr Heinz Tobien for casts of the Wölfersheim tooth and comments on the manuscript; Dr Oldrich Fejfar for helpful comments, and Mr Raymond Gooris for the drawings.

Adherence of *Escherichia coli* to human mucosal cells mediated by mannose receptors

THE colonisation of bacteria on human mucosal tissues is now recognised as an important step in the infectious process[1,2]. To colonise mucosal surfaces, the organisms must first bind to the epithelial cells of these tissues, or they are discarded by the host's physico-anatomical defence mechanism (sneezing, coughing, urine flush and so on). The attachment of bacteria to epithelial cells can be demonstrated *in vitro*[3,4] and is probably mediated by surface components of both types of cell[3]. It was found[4,5] that lipoteichoic acid on the surface of group A streptococci is responsible for the attachment of these organisms to oral mucosal cells. For Gram negative organisms, pili mediate their binding to epithelial cells[6–9]. In a study with *Proteus mirabilis* it was found[10] that the presence of pili is important for the organisms to adhere to both oral and bladder mucosal cells as well as to initiate retrograde infection in experimental animals, probably by enabling the bacteria to adhere and to colonise pelvic epithelial cells[11]. Nothing is known, however, about the putative receptor sites required for bacterial attachment on the mucosal cell membrane. We present here data indicating that attachment of *Escherichia coli* to epithelial cells is mediated by mannose (or mannose-like) receptors present on the surface of the latter.

In vitro adherence was studied by methods described previously[4]. Briefly, 0.5 ml of a suspension of epithelial cells (10^6 cells per ml in phosphate buffered saline, 0.1 M PO_4 and 0.15 M NaCl, *p*H 7.2–7.4) from the oral cavity of one of us (I.O.) was mixed with 0.5 ml of washed bacterial cells (*E. coli* strain 3092, a K_{12} derivative[12], or strain B, adjusted to 5×10^9 organisms per ml, or group A type 12 streptococci, 2×10^8 organisms per ml). The mixture was rotated end over end for 30 min at room temperature, then non-adherent bacteria were separated from the epithelial cells by differential centrifugation. The pellet of epithelial cells obtained after four washings with water was resuspended in 0.05 ml phosphate-buffered saline and placed on a slide. After drying, the preparation was stained with gentian violet and examined using light-field microscopy. Adherence was recorded as percentage of epithelial cells containing 50 bacteria or more. When the K_{12} or B strains of *E. coli* cells were mixed with a suspension of epithelial cells, the bacteria bound avidly to the cells (Fig. 1*a*) as shown previously for streptococci[4,5]. Only *E. coli* cells collected in the late stationary phase or from cultures 24–72 h old, were attached to the epithelial cells.

D-Mannose and methyl α-D-mannopyranoside (αMM) inhibited the adherence to the epithelial cells of both strains of *E. coli* but not of streptococci (Table 1). None of the other sugars tested inhibited epithelial binding of these organisms. The inhibition by αMM of adherence was dose related and was linear in the range of 2–6 mg sugar per ml. In the presence of αMM (25 mg ml^{-1}) the *E. coli* cells did not adhere; they were separated from the epithelial cells and each type of cell was washed three times to remove the αMM. On remixing the cells, epithelial attachment of the bacteria was restored, indicating that the inhibition of adherence by the sugar is reversible and probably does not involve any irreversible alterations on either type of cell.

Our observations suggest that saturation of binding sites on the bacterial surface by a sugar prevents the attachment of these organisms to the epithelial membrane receptor, which contains mannose or a mannose-like structure. This conclusion is supported by the following results. (1)

Table 1 Inhibition of adherence of *E. coli* to epithelial cells by carbohydrates, lectins and oxidation with sodium metaperiodate

Inhibitor used*	Concentration in reaction mixture (mg ml^{-1})	% Adherence†
Methyl-α-D-mannopyranoside	25	5
	5.0	25
D-mannose	25	10
	5.0	30
D-galactose	25	99
N-acetyl-D-glucosamine‡	25	85
Wheat germ agglutinin	0.5	99
Peanut agglutinin	0.5	75
Concanavalin A	0.5	28
Oxidation of epithelial cells with sodium metaperiodate§		0

*The sugars or lectins[13, 14] were incubated with suspensions of epithelial cells and bacteria for 30 min at room temperature, then treated as described in text.

†This was calculated as percentage adherence in the presence of sugars or lectins compared with control (without inhibitor) which was taken as 100% adherence.

‡The percentage adherence in the presence of other sugars (25 mg ml^{-1}) was in all cases >90%. The sugars tested were: D-rhamnose, L-fucose, maltose, D-glucose, methyl-α-D-glucopyranoside, and methyl-α-D-galactopyranoside.

§An epithelial cell suspension (0.5 ml, 10^6 ml^{-1}) was incubated with 10 mM of sodium metaperiodate for 10 min at room temperature. The cells were then washed twice with phosphate-buffered saline, resuspended in 0.5 ml of the same buffer, and mixed with *E. coli* suspension as described in the text.

Epithelial cells treated with sodium metaperiodate, a reagent known to cleave the C–C bond between vicinal hydroxyl groups of sugars, completely inhibited the binding of *E. coli* (Table 1) but did not affect binding of streptococci. (2) Concanavalin A, which is known to bind to D-mannose and D-gluscose residues[13], inhibited attachment to cell surfaces of *E. coli* but not of streptococci. The other lectins tested (wheat germ agglutinin—specific for *N*-acetyl-D-glucosamine (ref. 13), and peanut agglutinin—specific for D-galactose (ref. 14)) did not inhibit the binding of *E. coli* or of streptococci. (3) Both soluble yeast mannan and intact yeast cells, which are known to contain mannans on their cell surface[15], agglutinated *E. coli* cells (Fig. 1*b* and *c*). Incubation of a suspension of *E. coli* with mannan (7 μg ml^{-1}) or 10^5 yeast cells per ml, gave visible agglutination of the bacteria after 30 min, characterised by a diffuse carpet of cells on the bottom of the tube. Agglutination of *E. coli* by both mannan and yeast cells (*Saccharomyces cerevisiae*) could be completely blocked by D-mannose or by αMM at a concentration of 25 mg ml^{-1}, but not by any other sugar tested at the same concentration.

Addition of D-mannose or αMM (25 mg ml^{-1}) to epithelial cells to which *E. coli* was preattached caused rapid (within 2–5 min) displacement of the organisms from the epithelial cells. After washing the epithelial cells four times with a solution containing αMM (6 or 12 mg ml^{-1}), 55 and 85%, respectively, of the preattached bacteria were removed from the cells. Likewise, mannan (2 mg ml^{-1}) removed bacteria attached to the epithelial cells (Fig. 1*b*), but D-glucose, glycogen or D-galactose did not displace the bacteria.

Our results suggest that the binding of *E. coli* to epithelial cells is mediated by a mannose-specific, lectin-like substance present on the surface of *E. coli* which binds to a mannose-like receptor site on the mucosal cell. Indeed, extraction of *E. coli* K_{12} cells (1 g wet weight) with phosphate-buffered saline, adjusted to *p*H 8.5 (1 ml) at room temperature, gave a solution which contained a lectin-like substance specific for mannose, as shown by the following findings: (1) The extract agglutinated yeast cells at a dilution of 1 : 20; (2) this agglutination was inhibited by D-mannose or αMM (3 mg ml^{-1}) but not by any of the other sugars listed in Table 1 (25 mg ml^{-1}); (3) the extract, at 1 : 80 dilution, inhibited attachment of *E. coli* to epithelial cells; (4) the latter inhibitory activity was abolished by adsorption with yeast cells; (5) the agglutinating activity of the extract was stable to 59 °C (30 min), but was destroyed at 70 °C (30 min), or by treatment with trypsin (0.3 mg ml^{-1}, 2 h, 37 °C). Further work on the purification and characterisation of the *E. coli* lectin-like substance is in progress.

Production of mannose-specific lectins by members of Gram negative organisms, including strains of *E. coli*, has been reported[16–19]. In most of these studies the target host cell was the erythrocyte. Duguid *et al.*[16] reported that mannose inhibited binding of *E. coli* to intestinal epithelial cells, but this was not investigated in any detail and was overlooked in subsequent studies[2]. In agreement with the epithelial binding reported here, the bacterial haemagglutination was very weak in the logarithmic phase of growth and became strong only at 24–48 h growth[19].

Our report provides evidence suggesting that the mannose-specific bacterial haemagglutinins[16–19] enable the organisms to attach and colonise human mucosal tissues. Furthermore, mannose and its derivatives, which act as receptors for *E. coli* binding, can compete with the epithelial membrane-bound mannose to dissociate the organisms from the cell surfaces. Studies with concanavalin A suggest that mannose is widely distributed on the membrane of mammalian cells[13]. It would seem therefore that the normal distribution of Gram negative organisms on different mammalian mucosal tissues is not due to the presence or lack of the mannose receptor on epithelial cells. This is supported by the findings that, although the ileum rather than the jejunum of the gut is normally colonised by *E. coli*, the epithelial cells from both regions

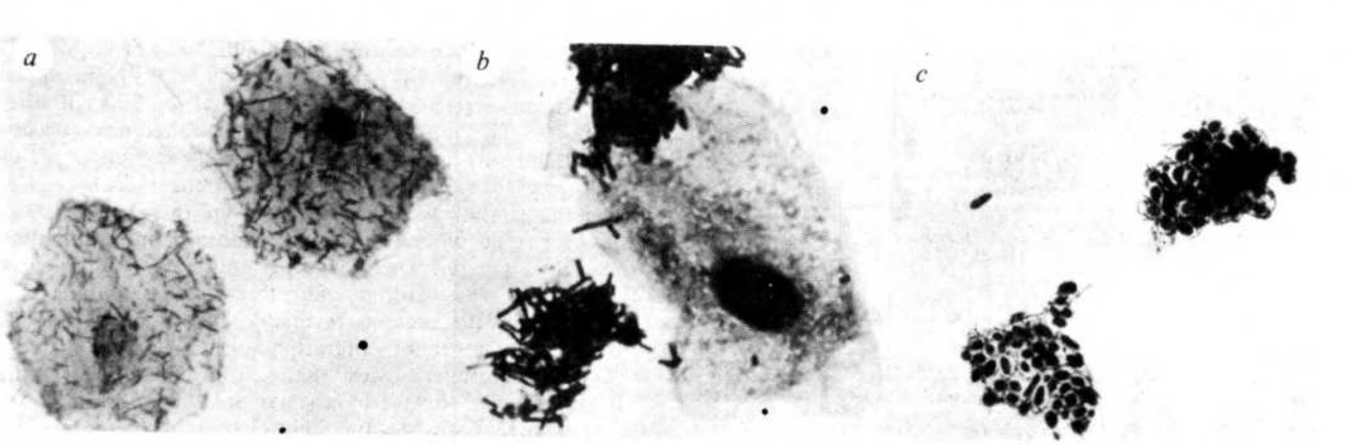

Fig. 1 Binding of *E. coli* to: *a*, human epithelial cells (×400); *b*, yeast mannan (Sigma) after removal from epithelial cells (×1,000); and *c*, yeast cells (*Saccharomyces cerevisiae*).

bound *E. coli* equally well[19]. The mechanism of attachment of streptococci to epithelial cells is different from that of *E. coli*, for none of the sugars tested inhibited the lipoteichoic acid-mediated streptococcal attachment[4,5]. In this regard it has been suggested that certain human tissues, such as sections of heart valves, lack receptors for *E. coli* but not for streptococci[21].

In conclusion, our finding that mannose, a sugar found on most mammalian cell surfaces, acts as receptor for binding of *E. coli*, which is one of the most common commensals of man, may provide an approach to the elucidation of the mechanism of bacterial adherence and subsequent colonisation on mucosal tissues.

Suppression by heparin of smooth muscle cell proliferation in injured arteries

INTIMAL smooth muscle cell (SMC) proliferation dominates the early phase of healing after arterial endothelial injury[1-6]; what growth factors are responsible for this mitotic activity of an otherwise quiescent cell is not known. SMC growth *in vitro* is enhanced by platelet factors, insulin and lipoproteins[7-11] and, according to some reports, can be diminished *in vivo* with various antiplatelet agents. Harker *et al.*[8] have reported decreased myointimal thickening in homocystinaemic baboons treated with dipyridamole, and Friedman *et al.*[11] and Moore *et al.*[12] have reported suppression of SMC proliferation in the injured arteries of rabbits injected with anti-platelet serum. Intimal thickening was not diminished, however, in the injured carotid arteries of rats given various anti-platelet drugs[13]. Because the clotting system is inextricably linked to arterial injury and because thrombin is used to generate the platelet growth factor[9] and may itself be a mitogen[14-16], we speculated that heparin might inhibit myointimal thickening. We report here the use of heparin to suppress intimal SMC hyperplasia in a rat model of arterial endothelial injury and suggest possible mechanisms for the heparin effect.

Endothelial injury was achieved by infusing air into isolated segments of right carotid arteries of 45 young male Sprague–Dawley rats (250–300 g, Charles River Breeding Laboratories) as described earlier[1,2]. This procedure dessicated the endothelium. After blood flow was re-established and haemostasis obtained, the wound was irrigated with Betadine solution. Using a sterile technique, a silastic catheter was inserted into the left jugular vein and connected to an infusion system as described by Steiger *et al.*[18]. Initially all rats were infused with lactated Ringer's solution (Abbott) at 0.91 ml h^{-1} using a syringe infusion pump. After 24 h, experimental rats were switched to an infusion of heparin (from pig intestinal mucosa, Elkins-Sinn). Control rats were infused continuously with Ringer's solution. Animals were killed at 5, 10 and 14 d by perfusion fixation[1,2] after blood had been collected for clotting times[17] and platelet counts. Carotid arteries were further fixed and processed as described earlier[1,2] for light, scanning (SEM) and transmission electron microscopy (TEM).

Clotting times were prolonged in a predictable fashion; as noted before[18], a linear relationship existed between the logarithm of the clotting time and the heparin dose. Heparin doses of 50 or 100 U kg^{-1} h^{-1} given intravenously yielded clotting times of 12.5 and 36 min (control 4.4 min). Platelet counts were not affected by heparin administration (control. 1.28 ± 11 × 10^6 (± s.e.); 50 U kg^{-1} h^{-1}: 1.38 ± 0.04 × 10^6; 100 U kg^{-1} h^{-1}. 1.38 ± 0.11 × 10^6).

In earlier studies on uncatheterised control animals[1,2], we showed that after carotid injury the dessicated endothelium rapidly sloughed and was supplanted by a carpet of platelets. Endothelial regeneration proceeded from normal endothelium at the ends of the injured segment and was complete by 14 d; between 5 and 14 d smooth muscle cells migrated through the internal elastic lamina and proliferated in the intima. The intimal thickness was maximal at 14 d.

The right carotid arteries of catheterised control animals at 5 d demonstrated partial endothelial regeneration and a dense monolayer of platelets in the residual central denuded portion of the injured segment. Unlike uncatheterised controls, at 10 and 14 d, endothelial regeneration in catheterised control carotids was still incomplete in the central zone; in place of endothelium and platelets, modified smooth muscle cells lined the luminal surface. A possible explanation for this failure of endothelial regeneration is that in stressed animals or after long arterial injuries[4,11], rapidly growing SMC can temporarily form a luminal surface and impede endothelial regeneration. At 10 d, all injured carotids showed marked intimal thickening due to SMC proliferation; at 14 d, the intimal thickening was even more pronounced. The injured right carotids of heparin-treated rats exhibited the same features as catheterised controls at 5 d with partial endothelial regeneration at the ends and a dense carpet of platelets in the middle of the injured segment; the platelets in heparin-treated rats were morphologically (SEM and TEM) similar to controls. At 10 d, a small central residual zone of denudation covered by platelets remained and at 14 d endothelial regeneration was complete as in uncatheterised controls. At 10 d there was only slight evidence of intimal thickening which nevertheless was not significantly different from controls. But, at 14 d, because of increased intimal thickening in control carotids, the maximum ratio of intima to media (I/M) in carotids from heparin-treated rats was diminished significantly (Fig. 1 and Table 1). The

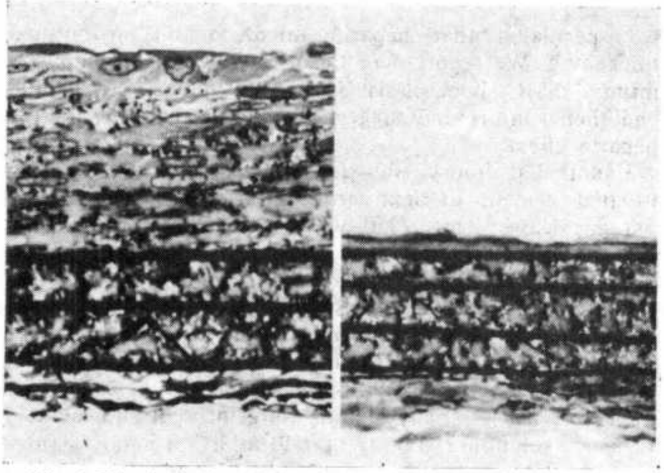

Fig. 1 Histological sections of injured right carotids in heparin-treated (right) and control (left) animals at 14 d. The maximum I/M ratio is 1.8 (control) and 0.2 (heparin). The minimal intimal thickening shown here in the right carotid of the heparin-treated rat is representative of findings in animals with a pronounced response to heparin; as can be seen in Table 1 there was considerable variation in intimal thickening under heparin treatment. TEM of these samples demonstrated only smooth muscle cells in the intima of the control carotid and a single layer of smooth muscle cells covered by endothelium in the intima of the carotid from the heparin-treated rat.

maximum I/M ratios for high and low dose heparin were similar and both were significantly different from control values. At most, one to three SMC layers were seen at this stage in the intima under the endothelium. The normal rate of endothelial regeneration in heparin-treated animals may have been related to the absence of luminal SMC.

These results indicate that heparin in doses sufficient to prolong clotting markedly suppressed intimal SMC proliferation after arterial endothelial injury even though endothelial regeneration (mitosis and migration) progressed unimpaired. Heparin did not seem to inhibit platelet-subendothelium interaction in the injured carotid.

This suppression of SMC proliferation may be the result of one or more effects of heparin because heparin is known to have many biological activities[19-21]. Heparin may act directly on the SMC[19,21]. Alternatively, because of its charge, heparin may bind and inactivate platelet growth factors generated by platelet activity on the denuded arterial wall; this is particularly plausible in view of Ross's *in vitro* results demonstrating that the SMC platelet mitogen is a basic protein[22]. Heparin may achieve several effects indirectly through its action on the clotting system. Thrombin and the other serine proteases of the clotting system (XII, XI, IX, X and plasmin) are undoubtedly activated at the surface of the denuded segment and may accumulate in the arterial wall. One or more of these clotting factors may be mitogenic for SMC[14,15]; thrombin, in particular, may generate mitogens from the adherent platelets as suggested by *in vitro* work[9,22]. Antithrombin III normally regulates the level of proteolytic activity by slowly inactivating the clotting proteases; this process is almost instantaneous in the presence of heparin[23]. Thus, heparin through antithrombin III may affect the degradation of platelets and generation of platelet SMC growth factors by thrombin[24], and the direct activity of the clotting proteases on SMC. Arterial SMC proliferation may be just one example of the general phenomenon of wound healing suppressible by heparin; previous studies of wounds in skin, bowel, artery and bone indicate that heparin can prevent scarring if given in doses large enough to produce a continuous and significant state of anticoagulation[25-28].

Table 1 Myointimal thickening at 14 d

	I/M
Control	1.9 ± 0.5 (5)
Heparin (50 U kg^{-1} h^{-1})	0.4 ± 0.2, $P = 0.02$ (5)
(100 U kg^{-1} h^{-1})	0.6 ± 0.1, $P = 0.005$ (10)
Total	0.5 ± 0.1, $P = 0.0007$ (15)

I/M ± s.e. was measured in right carotid arteries, 14 d after injury, which were cross sectioned at 500-μm stages along their entire length[2,13]. Because the thickened intima at 14 d is almost entirely composed of smooth muscle cells[1-6] (Fig. 1), the maximum I/M ratio reflects the amount of SMC proliferation and is measured by using an ocular graticule by taking the ratio of the maximum intimal thickness (distance from the luminal surface to the internal elastic lamina) to the adjacent media thickness (distance from the internal elastic lamina to the most external elastic lamina). Numbers of rats in each group are shown in parentheses.

In vitro culture and differentiation of normal mouse blastocysts

WHEN preimplantation mouse embryos are transplanted to extrauterine sites, up to 20% develop almost normally to the egg cylinder stage (equivalent to about 6–7 d *in utero*). They then become disorganised and give rise to tumours, which are usually mature teratomas containing a wide range of differentiated tissues, but less frequently are progressively growing teratocarcinomas containing nests of undifferentiated pluripotent embryonal cells[1,2]. There are many reasons why it would be interesting to reproduce such normal and abnormal development efficiently *in vitro*. Although a number of techniques have been used to culture preimplantation embryos, none of them has proved entirely satisfactory[3-5]; in the best conditions only 5–20% of 3.5–4-d blastocysts develop *in vitro* to form differentiated, foetal tissues. Most only give rise to extraembryonic endoderm and its associated mesoderm; these cell types proliferate extensively *in vitro*, and consequently most of the continuous lines derived from blastocyst cultures have probably originated from extraembryonic tissues[6]. In this paper we describe a simple and reproducible method for culturing mouse blastocysts *in vitro* so that around 70% give rise to colonies which continue to grow for up to 4 weeks and produce a variety of differentiated tissues, including skin, nerve, beating muscle, cartilage and fibroblasts. The method relies on the technique of immunosurgery[7] for killing and removing first the trophectoderm and then the hypoblast (primary endoderm) layers of the embryo, to yield clumps of isolated epiblast (embryonic ectoderm) (Fig. 1).

What subsequently happens to the epiblast cells depends entirely on the exact conditions in which they are grown. When they are incubated in bacteriological dishes so that they cannot adhere to the substratum they degenerate within 24 h. When incubated in tissue culture dishes, however, they rapidly adhere and spread out to form a sheet of cells surrounding a central clump (Fig. 2*a*); at 48 h some cell division is still occurring, but each colony finally degenerates by about day 4. The viability of these cultures cannot be improved by coating the dishes with gelatin.

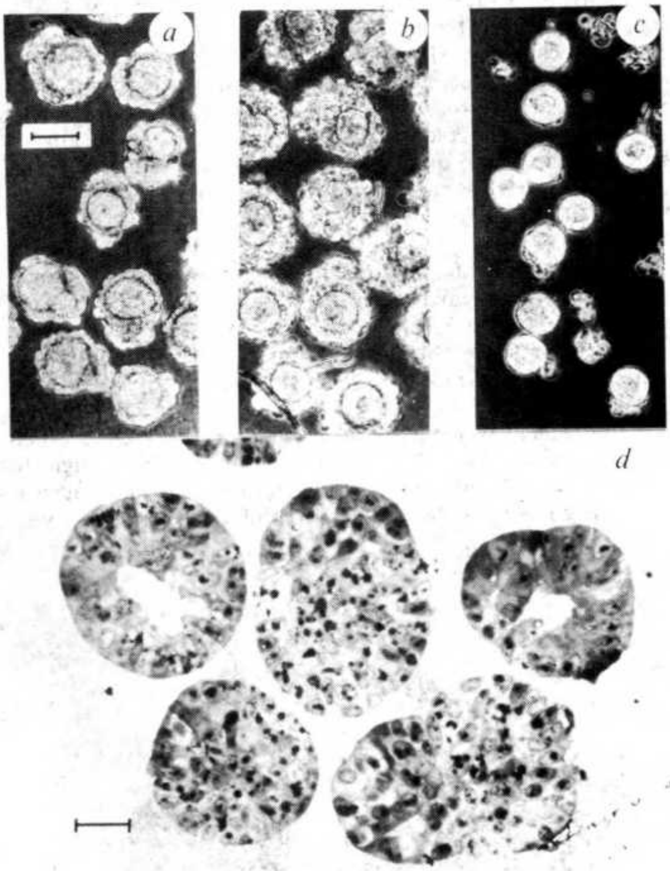

Fig. 1 Cultured embryos before and after removing the hypoblast layer by immunosurgery. Blastocysts are flushed from the uteri of C3H mice on day 4 of pregnancy and, after removal of the zonae pellucidae with Pronase[8], are incubated overnight at 37 C in a humidified atmosphere of 95% air/5% CO_2 in Dulbecco's modified Eagle's medium (DMEM) with either 10% foetal calf serum or 20% human cord serum (HCS, heat inactivated for 30 min at 56 C). Next day, the embryos are transferred to DMEM containing rabbit anti-C57BL mouse spleen antiserum[7] diluted 1:50. After 30 min at 37 C the embryos are washed twice in DMEM with 0.5% bovine serum albumin (BSA, Sigma fraction V) and transferred to a solution of guinea pig complement (Wellcome, 1:10 dilution) and incubated for 30 min at 37 C, by which time all the outer trophectoderm cells have lysed. The embryos are washed once in DMEM plus 0.5% BSA and incubated in DMEM with 20% HCS. After 48 h all the inner cell masses have developed an outer layer of hypoblast cells and in some cases the inner epiblast cells have formed a hollow sphere (*a*). If the immunosurgery procedure is repeated the hypoblast cells are lysed (*b*) and can be removed by pipetting the embryos up and down in a finely drawn Pasteur pipeett (*c*). Most of the isolated epiblast cell masses are solid, a few are hollow and a very few are asymmetric, with a cluster of larger, more densely staining cells to one side (*d*). Of 27 epiblast masses serially sectioned at 1 μm, all had an almost continuous outer layer of basement membrane material and the few hypoblast cells still attached were clearly dead. *a*, *b* and *c*, Phase-contrast microscopy (bar: 100 μm); *d*, isolated epiblast cells, fixed in 2.5% glutaraldehyde post-fixed in OsO_4 and embedded in Araldite. Sections were cut at 1 μm and stained with Toluidine blue (bar: 25 μm).

When the stripped embryos are incubated in the presence of a monolayer of mouse feeder fibroblasts about 70%

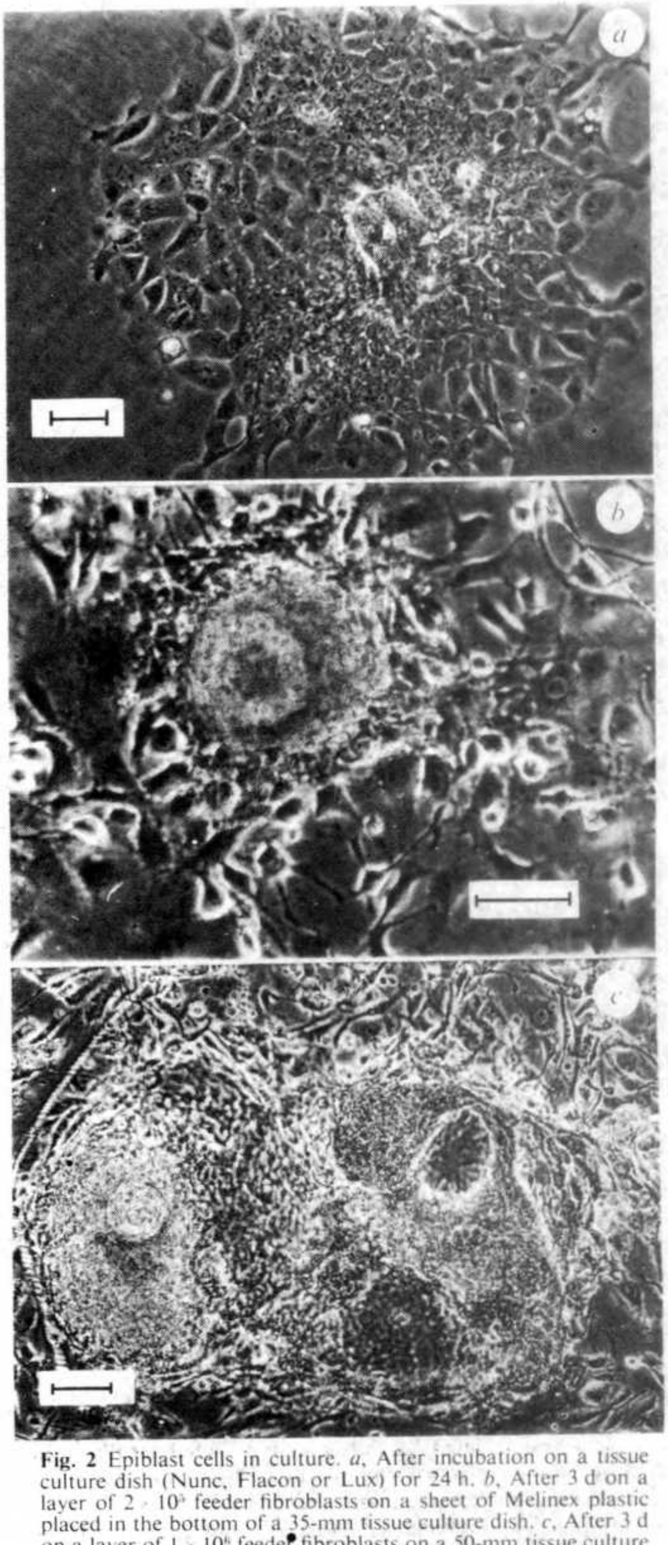

Fig. 2 Epiblast cells in culture. *a*, After incubation on a tissue culture dish (Nunc, Flacon or Lux) for 24 h. *b*, After 3 d on a layer of 2×10^5 feeder fibroblasts on a sheet of Melinex plastic placed in the bottom of a 35-mm tissue culture dish. *c*, After 3 d on a layer of 1×10^6 feeder fibroblasts on a 50-mm tissue culture dish. All cultures were incubated in DMEM containing 20% HCS. The mouse fibroblasts were treated before plating out with Mitomycin C (10 μg ml^{-1}) for 3.5 h so that they could not divide. In a typical experiment, 20–30 epiblast cell masses were added per dish and the medium changed every 2 d. Phase-contrast microscopy (bar: 100 μm).

of them survive for up to 4 weeks and form colonies containing a variety of differentiated tissues. Even in the presence of the feeder layer, however, the epiblast cells are sensitive to the underlying substrate; to facilitate electron microscope studies, the stripped embryos were sometimes grown on feeder layers on Melinex plastic (Boyden Data Papers, London, UK) and on this substratum they form rounded and compact colonies (Fig. 2*b*). When the epiblast cells are placed on feeder layers on standard tissue culture plastic, they form colonies which are much more spread out, grow more rapidly in a disorganised way and form a variety of differentiated tissues (Fig 2*c*).

Nineteen embryos which had been incubated on Melinex for 3 or 4 d were serially sectioned and examined in the light and electron microscope. The colonies fell into three main categories (Fig. 3). The simplest consists of a flattened vesicle of cuboidal or columnar cells, often embedded in the feeder layer (Fig. 3*a*). The second category contains a similar hollow vesicle of cells but, in some planes of sections, this is seen to be disorganised and surrounded by clusters of other cells (Fig. 3*b*). The third category contains in addition, a second vesicle lined by flatter cells which laterally interdigitate and have more endoplasmic reticulum and microvilli. Both vesicles are surrounded by a thin basement membrane. The cuboidal cell vesicle often contains masses of cellular debris, sugesting that it is initially formed by cell death. The flatter cell vesicle contains floccular material, suggesting that it is secretory. The cells surrounding these vesicles have few intracellular organelles and are either in tightly packed clumps, or are stellate and touch only at limited areas, often through contact zones; the stellate cells closely resemble mesodermal cells of normal 8-day embryos[14]. At the surface of the colonies some of the cells are occasionally joined laterally by tight junctions and desmosomes to form an outer layer, but this does not resemble morphologically the primary endoderm layer formed when isolated inner cell masses are incubated *in vitro* (Fig. 1*a*).

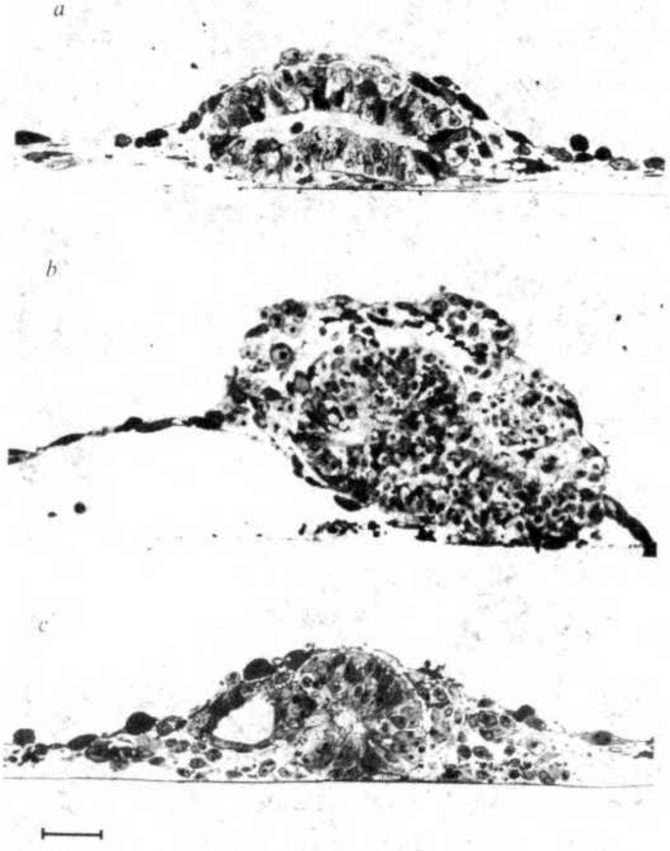

Fig. 3 Sections of epiblast cells grown on feeder fibroblasts on Melinex plastic, showing the three commonest forms of internal organisation. Epiblast cells were cultured for 3 d (*b*) or 4 d (*a* and *c*) and then fixed, sectioned and stained as described in Fig. 1*d*. In *a* and *c* the feeder fibroblasts form an almost continuous layer over the embryo; in *b* the embryo cells are on top of the feeder layer, which has partially detached from the Melinex (bar: 50 μm).

Colonies growing on feeder layers on tissue culture dishes are more spread out and, during the first few days of culture, can be seen to contain closely packed cells which resemble undifferentiated teratocarcinoma cells. Patches of fibroblast-like cells appear in most colonies by 4–5 d, together with convoluted ridges and vesicles of epithelial cells. Beating muscle and neurones are seen in about 20% of the colonies after a week in culture. Later many colonies contain clumps of large, rounded cells and also flattened cells with very large nuclei and granular cytoplasm. By 3 weeks, extensive sheets of fibroblast and epithelial cells may be seen. Seven colonies were examined histologically at around this time; all contained simple and squamous epithelium overlying mesenchymal tissue. Keratin pearls were found in two (Fig. 4*a*) and muscle and cartilage in one (Fig. 4*b*).

The experiments described here establish that isolated epiblast cells are able to differentiate *in vitro* into a variety of tissues. It seems, however, that this only occurs if the cells retain some three dimensional association following their isolation because if they are allowed to spread out into a monolayer they do not differentiate (Fig. 2*a*). The function of the feeder layer may be to provide growth factors which allow epiblast cell division to continue fast enough to counteract cell migration. If the feeder cells and embryos are plated out into separate halves of the same dish, most

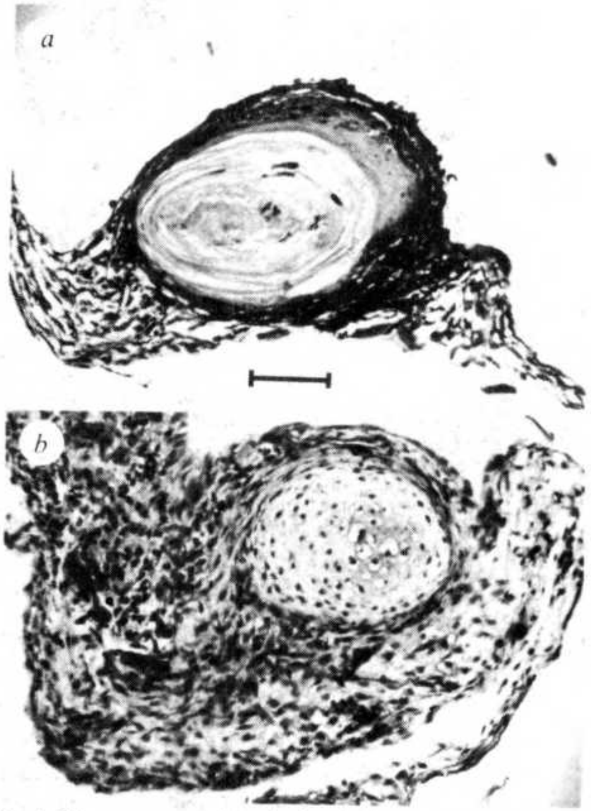

Fig. 4 Tissues present in colonies derived from epiblast cells incubated as described in Fig. 2*c*. Colonies were scraped off the dish, fixed in formal saline and embedded in wax. Sections were cut at 4 μm and stained with haematoxylin and eosin. *a*, Section showing a pearl of keratinised squamous epithelium in a colony which had been growing for 22 d. *b*, Section showing cartilage and muscle in a colony which had been growing for 17 d (bar: 50 μm).

of the epiblast cell masses still spread out and die, but a few (2/20) retain central clumps of cells and give rise to nerve, muscle, fibroblasts and skin.

The behaviour of isolated epiblast cells in culture provides several pieces of information about the way in which normal embryogenesis may be controlled. For example, the fact that mesoderm forms in the complete absence of a hypoblast layer shows that signals from the endoderm cells are not required for mesoderm differentiation. Similarly, because the epiblast cells do not reform an outer layer of primary endoderm, this suggests that either they are irreversibly committed to forming tissues other than endoderm; or they are not receiving the correct stimulus for this step under our culture conditions.

Several laboratories have studied the fate of embryonic ectoderm dissected manually from 8 d rat[11] or 6–7-d mouse[12,13] embryos and transplanted into extrauterine sites. In these sites the cells differentiate into teratomas and teratocarcinomas containing ectodermal and mesodermal tissues, as well as definitive endoderm tissues such as gut. This suggests that the endoderm of the mammalian foetus, like that of the chick[14], is being derived from cells of the epiblast and not from the hypoblast. So far we have not positively identified tissues of the definitive endoderm in our cultures, but it is possible that the formation of two vesicles in some colonies (Fig 3c) represents an attempt by the cells to make definitive endoderm

We are now using the method to isolate lines of early embryonic cells, including undifferentiated pluripotent cells equivalent to the embryonal cells of teratocarcinomas. The method may also provide a way of deriving cell lines from parthenogenetic embryos and from embryos of mice with mutations at the *T* locus.

We thank Gillian McArthur and James Vernon for assistance and Dr Marilyn Monk for invaluable help and discussion in the course of this work.

Parathormone-stimulated resorption of devitalised bone by cultured osteoclast-type bone cells

We recently reported the isolation from mouse calvaria of two different bone cell populations that express unique changes in metabolism when exposed in culture to parathormone and calcitonin[1–3]. In one cell type, termed *CT*, parathormone increased the synthesis of hyaluronate and the activity of acid phosphatase. In the second cell type, termed *PT*, parathormone inhibited citrate decarboxylation and decreased the activities of prolyl hydroxylase and alkaline phosphatase. Calcitonin blocked the effects of parathormone in the *CT* cells but not in the *PT* cells. Since the changes elicited in the separate populations by parathormone closely resembled those exhibited by calvaria maintained in organ culture[4], it seemed probable that the isolated cells retained unique properties in culture that are characteristic of their function in the intact tissue. On the basis of these results the *CT* cells were provisionally identified as osteoclasts and the *PT* cells as osteoblasts[3]. The major physiological result of the action of parathormone on bone *in vivo* or in culture is resorption of the calcified extracellular matrix, so we evaluated this function in the isolated bone cells. Should either the *CT* or *PT* cells promote resorption *in vitro*, this would further demonstrate that they retain differentiated function in culture and would aid in establishing their identity. We describe here a procedure which allowed us to test for resorptive properties of our isolated bone cell populations. We found that parathormone markedly stimulated the capacity of *CT*, but not *PT*, cells to resorb a calcified bone matrix substrate—a property in keeping with the identification of the *CT* cells as osteoclasts.

CT bone cells (populations 1 and 2) and *PT* bone cells (populations 4 and 5) were isolated from calvaria of 2–3-d-old mice and were maintained in primary culture for 7 d as described before[3]. They were then resuspended at 2×10^6 cells per ml in BGJ$_b$ medium[5] (Gibco), containing 5% foetal calf serum. Devitalised calcified matrix substrates were prepared from the calvaria of 3-d-old mice. After removal of extraneous tissue the calvaria were frozen at -20 °C for 3–5 d. Before use they were thawed at room temperature, then refrozen and thawed three times. In some experiments the starting calvaria were prelabelled *in vivo* with ^{3}H-proline and ^{3}H-hydroxyproline by obtaining them from pups of mothers that were injected with 250 µCi of [2,3-^{3}H] proline 1–2 d before delivery. These substrates were shown to be devitalised by their inability to resorb in culture conditions or to incorporate exogenous ^{3}H-thymidine and ^{3}H-leucine. The calvarial substrates were placed in individual wells of multi-well culture dishes (Linbro) and maintained in 5% CO$_2$ in air at 37 °C for 1 h. A 0.05-ml aliquot of the bone cell suspension (10^5 cells) was deposited in the concavity of each calvarium. Medium without cells served as a control. The cells and matrix were then incubated for 2 h (5% CO$_2$ in air; 37 °C) to facilitate cell adherence, after which they were covered with 1.0 ml of fresh BGJ$_b$ medium alone or containing parathormone 200 ng ml^{-1} (2×10^{-8} M) or calcitonin 110 ng ml^{-1} (3×10^{-8} M), or both. In some experiments 2.5×10^6 d.p.m. of ^{45}CaCl$_2$ at an initial specific radioactivity of 1.6×10^6 d.p.m. µmol^{-1} were included in this addition. The initial concentrations of calcium (Ca) and inorganic phosphate (Pi) in the incubation medium were 1.6 and 1.0 mM, respectively, and the *p*H was 7.4.

Culture was continued for 72 h. Histological examinations (our unpublished data) showed that the cells remained viable and formed a compact layer closely apposed to the surface of the bone matrix. Occasionally large multinucleated cells were seen in both populations, but more often in the *CT* layers. The medium was separated from the bone and analysed for Ca and Pi (ref. 6), ^{45}Ca and *p*H (at 37 °C, gas phase 5% CO$_2$ in air). To determine ^{3}H-proline and ^{3}H-hydroxyproline, samples of the media were hydrolysed for 24 h with 6 N HCl and samples of the hydrolysate were dansylated and chromatographed on thin-layer polyamide sheets[7] with carrier dansylproline and dansyl-hydroxyproline. The proline and hydroxyproline spots were cut out, eluted with 0.5 ml of 50% pyridine and radioactivity was assayed. The cells affixed to the calvarial matrix were tested after 72 h of culture for their capacity to synthesise ^{3}H-hyaluronate from [6-^{3}H]glucosamine and to decarboxylate [6-^{14}C]citrate, as described previously[3]. All assays of radioactivity were performed by liquid scintillation spectrometry[8].

Figure 1 summarises the results of growing bone cells on the bone matrix substrate for 72 h. With either the *CT* or *PT* cell populations in contact with the matrix there was release of Ca and Pi into the medium. In cultures of *CT* cells, however, there was substantially more ^{3}H-hydroxyproline release from

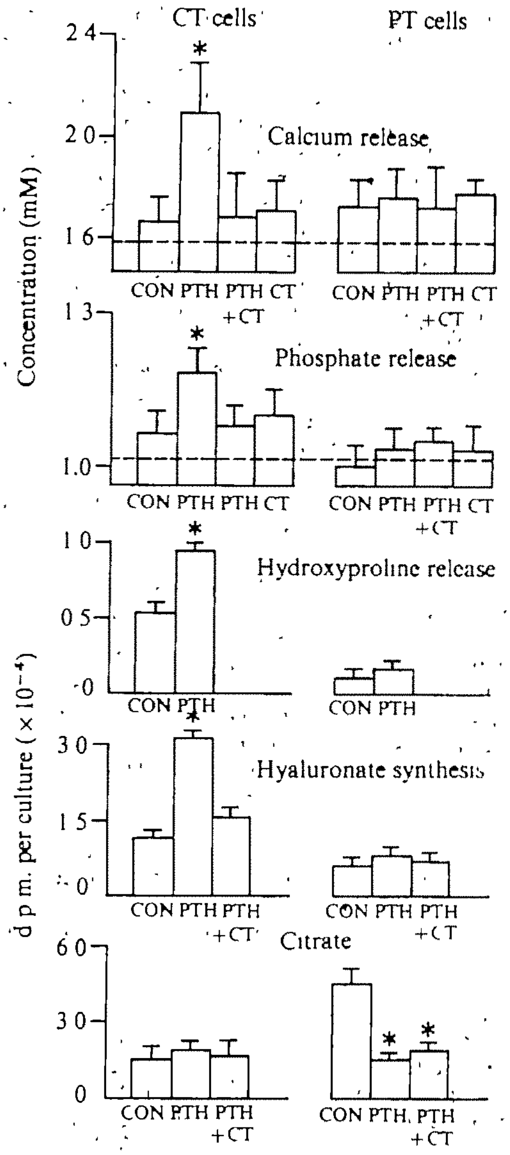

Fig. 1 Differential effects of parathormone and calcitonin on bone resorption by osteoclast-type (*CT*) and osteoblast-type (*PT*) isolated bone cell populations *CT* and *PT* cells were isolated and subcultured (10^6 cells per culture) on devitalised bone matrix for 72 h as described in the text. CON, no additions to the medium; PTH, parathormone 2×10^{-8} M; CT, calcitonin 3×10^{-8} M, PTH + CT, both hormones. Values are shown as means ± s e m of three to four cultures Baseline values shown for calcium, phosphate and hydroxyproline are those obtained when devitalised calvaria were cultured for 72 h without cells. Dashed lines denote the initial concentrations of calcium and phosphate in the BGJ_b culture medium. * = significant difference from CON, $P < 0.05$ (Student's *t* test)

prelabelled bone matrix. This indicates that in *CT* cultures resorption of collagenous matrix accompanied the dissolution of bone mineral to a greater extent than in *PT* cultures. This difference in resorption could not be correlated with differences in acidification of the medium by the cells (final *p*H in all cultures was approximately 7 2) or with differences in the uptake of ^{45}Ca by the matrix (final specific radioactivity in all cultures was approximately 0.9 d.p.m. μmol^{-1}). In cultures of matrix incubated without cells, there was a net transfer of Ca and Pi from the medium to the matrix. The *p*H did not change and no ^{3}H-hydroxyproline was released to the medium.

Parathormone markedly stimulated the resorption of Ca and Pi by the *CT* cells and calcitonin blocked this action (Fig. 1) The hormone also stimulated the release of hydroxyproline. These changes in resorption were not accompanied by any alteration in *p*H of the medium or uptake of ^{45}Ca. In contrast, parathormone or calcitonin alone or in combination exerted no significant effect on resorption of Ca and Pi by the *PT* cells. Figure 1 also shows that parathormone exerted its previously observed characteristic effects on the *CT* and *PT* cell populations[4]. That is, it stimulated hyaluronate synthesis in the *CT* cells but not *PT* cells and calcitonin blocked this action Parathormone inhibited citrate decarboxylation in the *PT* cells but not in the *CT* cells and calcitonin did not block this effect.

To establish that the action of parathormone was specific, we tested unrelated peptides and H_2O_2-oxidised (that is, biologically inactive) parathormone[9]. In three experiments, ACTH (1 U ml^{-1}), human somatotropic hormone (1 μg ml^{-1}), angiotensin II (1 μg ml^{-1}), and oxidised parathormone (1 μg ml^{-1}) were added to *CT* cells in culture with devitalised matrix as described above. Native parathormone was the control. In each experiment these peptides failed to elicit removal of calcium from the matrix by the *CT* cells.

These observations reinforce our earlier conclusion[4] that *CT* cells exhibit the characteristics of osteoclasts The findings that the resorption of devitalized matrix, by *CT* cells, but not by the *PT* cells, was stimulated by parathormone and that calcitonin inhibited this resorption are in keeping with what would be expected for osteoclasts acting *in situ*[10,11]. Our results also show that when both cell types are in contact with matrix there is a small amount of resorption in the absence of exogenous parathormone. The substantially larger release of hydroxyproline from the matrix by the *CT* cells, however, indicates that even in these basal conditions the *CT* cells function in a manner more analogous to osteoclasts *in vivo*. The basis for demineralisation of the matrix by the *PT* cells is not as clear It could be an inherent property of this cell type since osteocytes (probably derived from osteoblasts[12]) have been suspected of actively resorbing mineral[13] Our culture technique facilitates characterisation of the individual isolated cell populations in contact with the physiological matrix in varying conditions. This approach may permit precise characterisation of the molecular processes of bone development and turnover and its control by a variety of hormonal and nutritional factors.

T-cell-mediated cytotoxicity against herpes simplex virus-infected target cells

THE control of herpes simplex virus (HSV) infection by immunological mechanisms seems to be complex and is poorly understood Neutralising antibodies to HSV plus complement seem to have no effect on the propagation of HSV infection, because HSV spreads to adjacent cells by passing through intercellular bridges[1–5] Anti-HSV antibodies plus complement, however, destroy virus-infected cells, but cannot prevent the spread of HSV, suggesting that the virus must be transferred to neighbouring cells before immune lysis occurs[1,5] Therefore if lymphocyte-mediated cytolytic mechanisms are instrumental in blocking the spread of HSV *in vivo*, they ought to destroy infected cells at a very early stage in the viral maturation cycle, before infectious viral particles are produced. Indeed, effective antibody dependent cell-mediated cytotoxicity (ADCC) has been demonstrated *in vitro* using target cells infected with HSV[4,5]. In this system K-cell-mediated destruction of virus-infected cells takes place very early in the infectious cycle[5]. As *in vivo* protection against HSV infection is predominantly T-cell-dependent[6,7], the *in vivo* spread of HSV infections may be controlled by virus-specific cytotoxic T lymphocytes (CTL). But no virus-specific CTL so far have been detected in the spleen of HSV-infected mice. Using a different experimental approach we have now shown that T lymphocytes of mice undergoing a local HSV infection, when transferred *in vitro*, differentiate into effective CTL. The CTL generated are highly cytotoxic for HSV-infected target cells.

HSV type 1 strain Lennette was propagated in primary rabbit kidney cells as described before[8]. About $1–5 \times 10^5$ plaque-forming units (PFU) of HSV were injected into the hind footpad of CBA/J mice. After 3 d the draining lymph nodes (LN) were isolated and teased, and single-cell suspensions were prepared. The cells were cultured for a further 72 h at 37 °C, a period required to facilitate full differentiation of the sensitised CTL precursors (K. P. *et al.*, to be published). Thereafter, the LN cells were tested for the presence of virus-specific CTL in a 6-h cytotoxicity assay[9] using thioglycollate-induced ^{51}Cr-labelled, HSV-infected CBA macrophages as targets. The syngeneic target cells were infected *in vitro* with 2–5 PFU of HSV per cell 16 h before the ^{51}Cr assay.

Representative results obtained in 17 experiments of this type are shown in Table 1. Accordingly, LN cells draining the site of a local HSV infection *in vivo*, when transferred *in vitro*, differentiated into cytotoxic lymphocytes (CL) with strong lytic activity towards HSV-infected syngeneic macrophages. In contrast, LN cells draining a site which had been injected only with culture medium (control) did not develop cytolytic activity. Pretreatment of CL with anti-Thy 1.2 serum plus complement abrogated their cytotoxic activity (Table 2), strongly suggesting that the CL were T cells. LN cells not removed 3 d after local HSV infection and cultured for 3 d *in vitro*, but obtained *in vivo* 6 d after infection, showed only marginal cytotoxic activity. On the other hand, LN cells draining a local HSV infection until day 10, on transfer *in vitro*, generated effective HSV immune CTL.

Table 1 Lysis of HSV-infected syngeneic macrophages by HSV-induced cytotoxic effector cells

Experiment no.	*In vivo* sensitisation	% Lysis of ^{51}Cr-labelled macrophages: HSV-infected 50 : 1*	HSV-infected 5 : 1	Normal 50 : 1	Normal 5 : 1
	HSV	77	31	11	2
165	Culture medium	−2	1	−3	−1
	HSV	66	26	22	4
179	Culture medium	−4	+1	0	0
	HSV	46	21	42	20
172	Culture medium	−1	0	0	−2

CBA mice received either a given concentration of Lennette strain of type 1 HSV virus in Dulbecco's modified Eagle's medium (DMEM) or DMEM alone by injection in the hind footpad. After 3 d the draining LNs were dissected, single-cell suspensions were prepared and the cells were cultured for additional 72 h in DMEM supplement with 5% foetal calf serum (FCS). The LN cells were then tested for cytotoxicity at various ratios of attacker cells to target cells against ^{51}Cr-labelled syngeneic macrophages[9]. The thioglycollate-induced CBA macrophages were either HSV-infected or non-infected. HSV-infected macrophages were prepared by exposing the cells to Lennette strain type 1 HSV at a multiplicity of infection of 2–5 PFU per cell at 37 °C in DMEM plus 5% FCS for 1 h at 37 °C. The infected macrophages were washed and incubated for additional 15 h at 37 °C. Assay time of the ^{51}Cr cytoxicity test (using 2×10^4 target cells) was 5–6 h. Background lysis of the infected or non-infected macrophages was less than 31%. The percentage lysis data were calculated as before[9]. Of a total of 17 experiments performed, three representative experiments are detailed.

*Ratio of attacker cells to target cells.

Table 2 Effect of anti-Thy 1.2 serum plus complement

Treatment of cytotoxic lymphocytes	% Lysis of HSV-infected CBA macrophages 40 : 1*	4 : 1
None	66	31
Complement alone	70	40
AKR anti-Thy 1.2 serum plus complement	6	3
AKR-serum plus complement	67	38

Cytotoxic lymphocytes towards HSV-infected targets were raised as described in Table 1. The cells were divided into four groups; one group remained without treatment, the others were treated either with complement, anti-Thy 1.2 serum plus complement or with normal AKR serum plus complement. The remaining cells were tested in a 4.5-h ^{51}Cr assay for cytotoxicity towards HSV-infected CBA macrophages (2×10^4) at a cell dilution resulting in the ratio of CL to targets given (for the untreated group). Background lysis of the targets was less than 27%.

*Ratio of CL to target cells.

In four of 17 experiments the CTL generated were almost equally cytotoxic for non-virus-infected, normal syngeneic macrophage targets as for virus-infected cells (see experiment 172, Table 1). This result *a priori* would contradict a possible virus specificity of the CTL generated. In most experiments, however, the CTL generated lysed non-infected syngeneic targets only to a limited extent (experiments 165 and 179; Table 1), so the possibility of the existence of HSV-specific CTL was investigated further.

Because in the above experiments the CTL were assayed for cytotoxic activity in a 6-h ^{51}Cr assay, and because HSV surface antigen was expressed on infected macrophages as early as 2–3 h after infection (K. P. *et al.*, to be published),

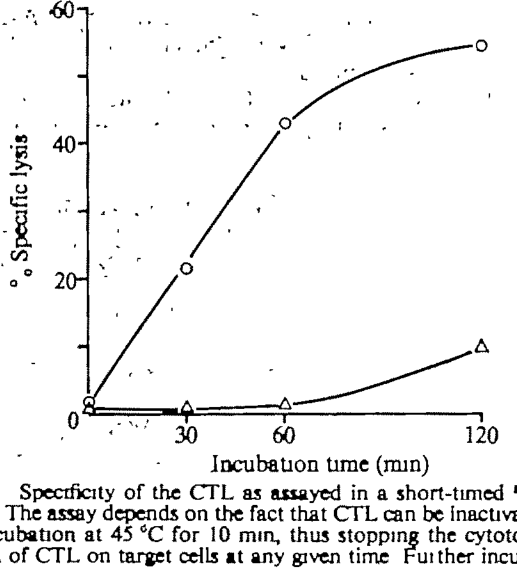

Fig. 1 Specificity of the CTL as assayed in a short-timed ^{51}Cr assay. The assay depends on the fact that CTL can be inactivated by incubation at 45 °C for 10 min, thus stopping the cytotoxic action of CTL on target cells at any given time. Further incubation for 3 h will lead to the manifestation of the previously set cytotoxic action (for details see ref. 10). CBA mice were injected with $1–5 \times 10^5$ PFU HSV into the hind footpad. Three days later the cells of the draining LN were prepared, cultured for additional 72 h *in vitro* and then tested for cytotoxicity towards HSV-infected[1] (○—○) or non-infected[2] (△—△) target cells (2×10^4). Replicates of mixtures of CTL and target cells were set up at a ratio of 50:1 and incubated at 37 °C. At each of the time intervals indicated, triplicates of the two experimental groups were transferred for 10 min to 45 °C, and then incubated for 3 h at 37 °C. Percentage specific lysis was calculated as before[9]. For control 1, cytotoxic activity of CTL to HSV-infected macrophages at 37 °C over 4 h was 62%. For control 2, cytotoxic activity of inactivated CTL (10 min at 45 °C) at 37 °C over 4 h was 2%. Background lysis of the targets was less than 28%. Similar results were obtained in five independent experiments.

it is possible that an infection of 'normal' macrophage targets may take place during the 6-h ^{51}Cr assay. Infectious HSV particles carried over during the ^{51}Cr test from the effector cell population to the 'normal' macrophage targets would thus induce an intra-experimental HSV infection of normal targets, and render them susceptible to the cytolytic action of the CTL generated. We therefore tested for virus-specific cytotoxicity in an experimental system in which the time of contact between CTL and target cells could be reduced to less than 1 h In such assay conditions only targets which had been infected before the onset of the ^{51}Cr assay would be lysed.

The T-cell-mediated cytolytic effector phase can be dissected experimentally into a T-cell-dependent short-timed phase of antigen recognition and lethal hit, and into a T-cell-independent time-consuming phase of cytolysis[9]. It is therefore experimentally possible to reduce the time of interaction between CTL and the respective target cells to less than 1 h[10]. We used this approach in the HSV-system The results (Fig. 1) clearly indicate that a contact time between CTL and HSV-infected targets of less than 1 h was sufficient for strong lysis of the targets More important, the cytolytic activity of the CTL was restricted to HSV-infected targets In these conditions, no lysis of normal targets was detected Further studies showed that the lytic activity of HSV-specific CTL generated with the methodology described is restricted to recognition of HSV antigens in the context of syngeneic histocompatibility antigens (H-2 restriction).

T lymphocytes of mice draining a local site infected with HSV therefore differentiate *in vitro* into CTL In a short-timed cytotoxicity assay these CTL are cytolytic for HSV-infected syngeneic targets Non-infected syngeneic targets are not lysed. *In vitro* HSV-infected syngeneic targets are effectively destroyed by HSV-induced CTL, so such cells may be involved in controlling the *in vivo* spread of HSV infection Because HSV-induced CTL lyse syngeneic targets as early as 2–3 h after infection and because HSV replication in infected cells requires at least 8–12 (ref 5) HSV-induced CTL may be cytotoxic towards infected targets well before viral progeny is produced

Insulin inhibition of antibody-dependent cytoxicity and insulin receptors in macrophages

INSULIN receptors have been demonstrated on various human white blood cells, including monocytes[1,2] granulocytes[3] and cultured lymphoblastoid cells[4]. Of these, the insulin receptor of the monocyte, a circulating macrophage, has been the most useful in the study of human disease[5-7], although insulin has no known effect on macrophage function We demonstrate here that cultured mouse macrophages[8] and macrophage-containing cell populations from normal mouse spleens both possess specific receptors for insulin with properties indistinguishable from those of the human monocyte, and that insulin, at physiological concentrations, inhibits the ability of these cell populations to lyse antibody-coated red cells (antibody-dependent cell-mediated cytotoxicity or ADCC)

^{125}I-insulin binding to cultured tumour macrophages (P388D$_1$ cell line), mouse spleen cells and human mononuclear cells demonstrated properties which characterise classical insulin receptors[11-14]. The specificity of receptor binding was virtually identical for the three cell types (Fig. 1) Competition curves for ^{125}I-insulin binding by unlabelled porcine insulin revealed 50% inhibition of tracer

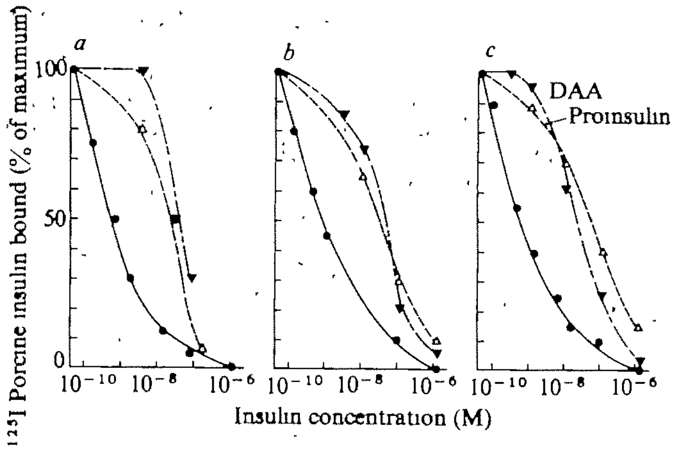

Fig. 1 Inhibition of ^{125}I-insulin binding by insulin analogues in *a*, human mononuclear cells, *b*, mouse spleen cells and *c*, cultured P388D$_1$ macrophages Human mononuclear cells were prepared using Ficoll–Hypaque gradients by Boyum's method[20] The preparations contained approximately 20% monocytes by the criteria of latex bead ingestion, and 80% lymphocytes Spleen cells were prepared from 6–10-week-old, DBA/2 male mice by a modification of the method of Mishell and Dutton[21] P388D$_1$ cells were maintained in Eagle's MEM supplemented with 10% foetal calf serum with fresh culture medium added every 48–72 g and were used for ^{125}I-insulin binding studies approximately 24 h after fresh medium was added Crystalline porcine insulin (Eli Lilly) was labelled with ^{125}I at a specific activity of 130–230 μCi μg^{-1} by a modification of the Hunter and Greenwood method[22-24]. Tracer amounts of ^{125}I-porcine insulin (0 2 ng ml^{-1}) were incubated with 4 × 10^{6} macrophages in 0 5 ml buffer (100 mM HEPES, *p*H 7.8 for P388D$_1$ and spleen cells or *p*H 8.0 for human monocytes) and increasing amounts of either unlabelled porcine insulin (●), unlabelled porcine proinsulin (△), or unlabelled DAA-insulin (▲) After 3 h of incubation (at 15 C for P388D$_1$ and spleen cells or 22 C for human monocytes), replicate 200-μl samples were transferred to microfuge tubes and centrifuged for 1 min. The resulting supernatant fluid was aspirated, the cell pellet was excised and the cell-associated radioactivity was counted Nonspecific binding (radioactivity bound to cells in the presence of porcine insulin, 100 μg ml^{-1}) was subtracted from total binding to yield specific binding. Maximum specific binding (100% value) for the human monocytes was 6%, for the mouse spleen macrophages 8% and for the cultured macrophages 13%

binding at 10^{-8} M for all three cell populations. Porcine proinsulin and desalanine desasparagine insulin (DAA-insulin), which have 1–5% of the biological activity of porcine insulin, were 1–5% as potent as porcine insulin in competing for ^{125}I-insulin binding to the insulin receptors of these cells (Fig 1). Thus, the receptors on all three cell types showed similar inhibition of insulin binding by insulin analogues with the receptor potency of the insulin analogue proportional to its biological activity.

In addition to specificity of binding, several physicochemical properties of the insulin receptors in these three cell populations were similar to more classical insulin receptors ^{125}I-insulin binding showed a sharp optimum at pH 7 8–8.0 The amount of ^{125}I-insulin bound in steady-state conditions increased with temperature in the order 4, 15, 22 and 37 °C. Both the association rate and the dissociation rate of ^{125}I-insulin binding increased with temperature, with the increase in the dissociation rate being greater than the increase in the association rate. Equilibrium analyses of insulin binding to the three populations of cells gave curvilinear Scatchard plots, and kinetic studies demonstrated that excess unlabelled insulin accelerated the dissociation of ^{125}I-insulin that had been bound previously to receptor These latter two findings indicate site–site interactions among insulin receptors of the negatively cooperative type[13]

Previous studies have shown that macrophages may act as effector cells in *in vitro*, antibody-dependent cytotoxicity assays[14–16]. We found that insulin inhibited ADCC in both the tumour macrophages (P388D$_1$ cell line) and the mixed cell population prepared from mouse spleens (Fig 2*a*, Table 1). Inhibition by insulin was most pronounced at low effector(macrophage)-to-target cell ratios (Fig. 2*b*, Table 1) At an effector-to-target cell ratio of 1 25 : 1, insulin at 10^{-8} M inhibited P388D$_1$-induced lysis by more than 70% and 10^{-10} M insulin inhibited lysis by 25% With the mouse spleen cells, at ratios of 2 5 : 1, 10^{-8} M insulin inhibited lysis by 29% and 10^{-10} M insulin inhibited lysis by 15%. In P388D$_1$ cells, the inhibition of ADCC by insulin was dose-related for a wide range of insulin concentrations (Fig. 3). In both systems, insulin concentrations as low as 10^{-10} M, which is clearly within the physiological range, produced a significant decrease in cell lysis. This inhibitory effect of insulin was reproducible in several experiments, the data in Figs 2 and 3 and Table 1 being representative.

In P388D$_1$ cells the inhibitory effect of insulin was exerted through the macrophages and not through insulin-induced alterations in target red cells When the P388D$_1$ cells were preincubated with insulin and then washed before exposure to target cells, the effect of insulin on ADCC was still observed If the target cells were first preincubated with insulin, thoroughly washed and then exposed to P388D$_1$ cells, however, ^{51}Cr release was not inhibited and was similar to that obtained in the absence of insulin (data not shown).

Both the mouse spleen cells and human mononuclear cells represent mixed cell populations. In the cell population prepared from mouse spleens, both insulin binding and cytotoxic activity seem to be due to the macrophages. When these spleen cells were depleted of macrophages by passage through a Sephadex G-10 column[17], insulin binding was decreased by 75% and ADCC was abolished (Table 1, depleted fraction) Moreover, when macrophage-enriched cells were eluted from the column before use, both cytotoxic activity and ^{125}I-insulin binding were restored (Table 1, enriched fraction). We previously found similar ^{125}I-insulin-binding results in enrichment and depletion experiments with the mixed mononuclear cell preparations from human blood; coupled with radioautography, these studies established that monocytes and not lymphocytes account for the observed insulin binding in this mixed cell preparation[3].

Macrophages from normal mouse spleens and cultured tumour macrophages (P388D$_1$ cell line) thus possess insulin receptors indistinguishable from those of the circulating human monocyte and other mammalian tissues. Furthermore, physiological concentrations of insulin alter a specific immunological function, antibody-dependent cell-mediated cytotoxicity, in both the spleen and tumour cells. In the spleen cells, insulin maximally inhibited ADCC by 30%, while in the more homogenous P388D$_1$ cells, insulin inhibited ADCC by more than 70%. The potency of insulin in the two cell systems may differ because spleen cells are a mixed cell population; multiple effector cells could exist in this preparation, with insulin acting on only a minority of the effector cells.

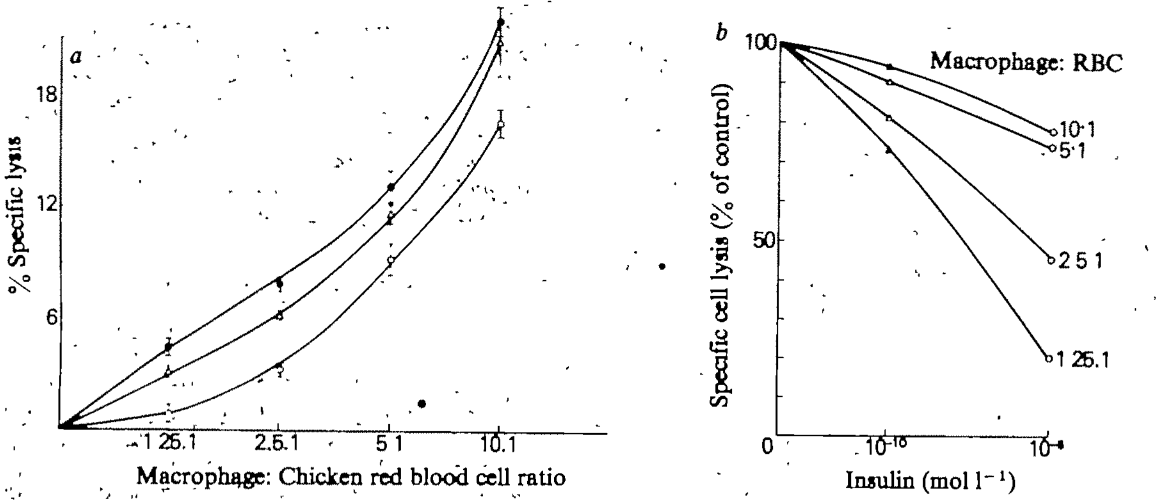

Fig. 2 *a*, The effect of insulin on antibody-dependent cytotoxicity in cultured tumour macrophages (P388D$_1$ cell line) Chicken red blood cells were labelled with ^{51}Cr and coated with anti-trinitrophenyl antibodies as previously described[15] The effector cells (P388D$_1$ cells) were preincubated with or without insulin at 37 C for 30 min Various concentrations of effector cells were then added to 5 10^4 target red cells in a final volume of 1 ml; and incubated at 37 C for 2 h. At the end of the incubation period the reaction mixture was centrifuged at 700*g* for 10 min at 4 °C The resulting supernatant was counted and specific cell lysis was calculated using the formula: percentage specific lysis $= (E - S)/(T - S) \times 100$, where E = counts of experimental group, S = counts from supernatant fluid of assay tubes containing only ^{51}Cr-labelled red cells (spontaneous release) and T = total radioactivity in assay tube. Spontaneous release in this experiment was 1.1%. Details of this ADCC assay have been previously described[15,18]. The percentage specific lysis by effector cells preincubated with buffer alone (●), with 10^{-8} M insulin ( ) and with 10^{-10} M insulin (△) are plotted for different ratios of effector:target cells All points represent the mean ± s.e. of triplicate samples. *b*, Inhibition of antibody-dependent cytotoxicity by insulin plotted as a function of effector–target cell ratios, which varied from 10:1 to 1:25·1. Lysis, calculated as percentage of buffer control at comparable effector–target cell ratio, is plotted as a function of insulin concentration.

Table 1 ADCC and ^{125}I-insulin binding in spleen cells from normal DBA/2 mice

ADCC by mouse spleen cells

E:T*	[Insulin] (M)	% Specific lysis†	% Inhibition of lysis‡	P

† Specific lysis calculated as described in Fig. 2. Spontaneous release in this assay was 7.3%.
‡ Calculated as percentage of control tubes without insulin.

The mechanism by which insulin alters macrophage-mediated ADCC is unknown. Rhodes has shown that insulin, at high concentrations (5×10^{-8} M) and over relatively long periods (72 h), decreases the number of F$_c$ receptors on peritoneal macrophages[18]. The initial step in ADCC involves recognition by the macrophage F$_c$ receptors of the F$_c$ portion of the antibody which coats the target cell, so alterations of macrophage F$_c$ receptors could decrease cell lysis. Whether insulin, at lower concentrations and over the shorter course of our experiments, could decrease the number or affinity of macrophage F$_c$ receptors is unknown.

Strom[19] has shown that physiological concentrations of insulin increase the cytotoxic potential of 'killer' T cells in a direct, lymphocyte-mediated cytotoxicity assay. Taken together with our findings, these observations suggest that insulin can alter the immune system at multiple levels. The *in vivo* significance of our findings, and the potential role of insulin in immune function, however, remain speculative. We suggest that the cell populations described in this report offer unique model systems for studying the interrelations between insulin receptors and an insulin-mediated biological effect on immune function.

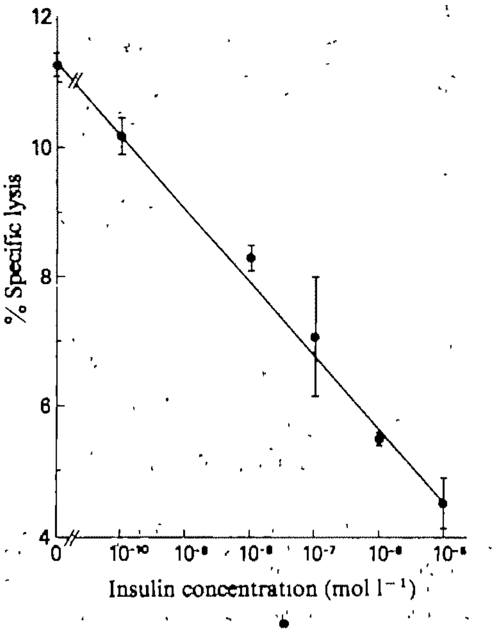

Fig. 3 Dose-response effect of insulin on antibody-dependent cytotoxicity in the cultured tumour macrophage. P388D$_1$ tumour cells were preincubated with various concentrations of insulin then assayed at an effector (macrophage)–target cell ratio of 5:1. Details of the assay are described in the legend to Fig. 2. Each point represents the mean ± s.e. of triplicate samples.

We thank Mrs Carolyn Siebert and Drs Jesse Roth, Matthew Rechler and John Wunderlich for advice. Dr R. E. Chance supplied porcine insulin, and Dr F. H. Carpenter provided DAA-insulin.

Effect of flavone inhibitors of transport ATPases on histamine secretion from rat mast cells

INTERACTION of multivalent ligands with receptors (immunoglobulin E, IgE) on the surface of the mast cell stimulates the calcium-dependent degranulation and secretion of histamine[1,2]. Secretion is also initiated by application of the calcium carrier substance (ionophore) A23187 (ref 3), and so the effective common stimulus to this cell (and many others) is the entry of Ca^{2+} ions into the cytosol. The mechanism of the normal ligand-induced calcium entry process is not well understood[4]. Certain flavones, notably quercetin, interfere with the activity of membrane transport adenosine triphosphatases (ATPases) including the calcium-dependent ATPase which is associated with exclusion of calcium from the cytosol of cells. They are not simple ATPase inhibitors but probably act by increasing the efficiency of ion translocation, thus reducing the consumption of ATP (refs 5, 6). Also, the flavones (2-phenyl cromones) have some structural resemblance to the widely used anti-allergic drug cromoglycate whose activity may be expressed at the calcium entry pathway[7]. We examine here the effect of these substances on histamine secretion from mast cells.

The effects of six flavones on antigen-induced histamine secretion are shown in Table 1. While two of these have little effect even at 100 μM, fisetin, quercetin, myricetin and kaempferol inhibit strongly at 33 μM. Fisetin, quercetin and myricetin interfere with transport ATPases while neither of the non-inhibitory flavones is active in this respect[8].

Since ionophore-mediated release bypasses the normal calcium entry pathway regulated by multivalent ligands[1], it distinguishes between inhibitors which act on or before calcium entry and those which affect a later stage in the secretory process[4,10]. Thus, whereas quercetin inhibits release stimulated by antigen and concanavalin A, which bind to IgE (refs 1, 9) (Fig. 1), release induced by ionophore A23187 is only slightly affected. It is unlikely that this latter effect arises from an action of the quercetin on the cells because (1) mixtures of A23187 and quercetin form visible precipitates; (2) the fluorescence emission spectrum of A23187 is red shifted in the presence of quercetin; (3) the permeability of liposomes rendered permeable to Ca^{2+} and Fe^{2+} with A23187 is reduced by the addition of quercetin.

Table 1 Effect of flavones (at 33 and 100 μM) on antigen-induced histamine secretion from rat mast cells and on Ca^{2+}-dependent ATPase activity of rabbit skeletal muscle sarcoplasmic reticulum

	Histamine secretion		Ca^{2+}-dependent ATPase activity	
	33 μM	100 μM	33 μM	100 μM
Fisetin	0.31	0.00	0.91	0.57
Kaempferol	0.59	0.24	0.64	0.30
Morin	0.99	0.82	0.95	0.74
Quercetin	0.37	0.00	0.69	0.37
Myricetin	0.42	0.26	0.74	0.37
Rutin	1.00	0.75	0.99	0.91

Results are expressed as a fraction of the control value obtained in the absence of flavone. Peritoneal mast cells purified to >80% homogeneity[19] were obtained from rats sensitised to egg white protein. Cells were preincubated at 37 for 5 min in Tyrode's solution containing 10 μM phosphatidyl serine before addition of the releasing agent and flavones. (The phosphatidyl serine was added to enhance the degree of ligand mediated secretion[20]). After 2 min the reaction was ended by addition of ice-cold saline, and histamine in the supernatant was measured fluorimetrically[21]. Any interference due to the flavones was compensated for by using appropriate blanks and standards. The Ca^{2+}-ATPase activity of rabbit muscle sarcoplasmic reticulum[22] was determined by measurement of the rate of H^+ release during ATP hydrolysis in a solution containing 250 mM sucrose, 100 mM KCl, 5 mM $MgCl_2$, 8.2 mM potassium oxalate, 15 mM sodium citrate, 2 mM ATP, 10 mM Tris buffer. The pH was adjusted to 7.5 and free calcium concentration was brought to 10 μM by addition of 0.4 mM $CaCl_2$. The reaction was initiated by addition of sarcoplasmic reticulum membranes, giving a final concentration of about 0.12 mg protein per ml. The specific activity of the preparation was about 1 μmol mg^{-1} min^{-1} at room temperature. Less than 10% activity was obtained in the absence of calcium.

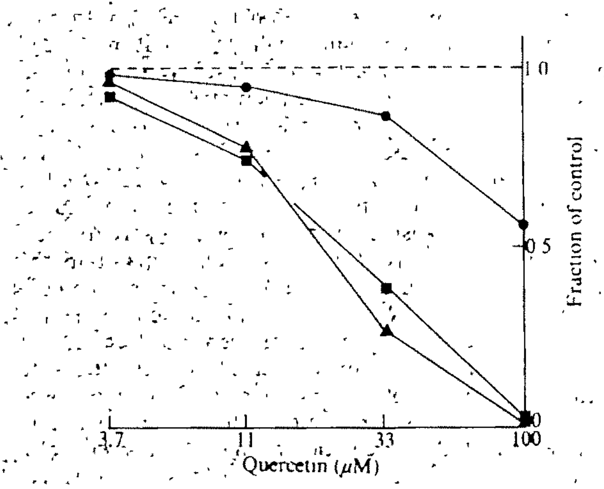

Fig. 1 Effect of quercetin on histamine release from mast cells stimulated with releasing agents. Methods are as in the legend to Table 1 except that the ionophore A23187, which is fluorescent, was extracted into hexane before histamine assay. Results are expressed as a fraction of control obtained in the absence of flavone. Mean s.e. ±0.04. ●, A23187 (5 μM) seven experiments; ■, antigen (10 μg ml^{-1} egg white protein) seven experiments; ▲, concanavalin A (10 μg ml^{-1}) five experiments.

Our results support the idea that the effect of quercetin on ligand-stimulated cells involves blockade of the normal calcium entry pathway. A similar argument explains the action of the phosphodiesterase inhibitors theophylline and dibutyryl cyclic AMP on mast cell secretion[7], and dibutyryl cyclic AMP was shown to prevent concanavalin-A-induced $^{45}Ca^{2+}$ uptake by T lymphocytes[11]. Inhibition of mast cell secretion by cromoglycate could be mediated by a similar mechanism[12]. Quercetin has negligible activity as an inhibitor of the cyclic AMP phosphodiesterase of human lung (J. Hare and I. F. Skidmore, personal communication) and unlike theophylline and dibutyryl cyclic AMP the effect of quercetin is manifest when it is added to the cells simultaneously with the releasing ligand. In this respect, it resembles cromoglycate, but, unlike quercetin, the effect of cromoglycate is of short duration[13], and is much less active on cells treated with phosphatidyl serine.

Our results indicate that we are dealing with a novel regulator of the calcium pathway.

At the concentrations used to inhibit mast cell secretion the activity of the flavones seems to be restricted to membrane transport ATPases[14,15]. The effective flavones alter the activity of several ATPases including plasma membrane $(Na^+ + K^+)$ ATPase of heart muscle[16], mitochondrial ATPase[15] and the Ca^{2+} ATPase of chloroplasts[17,18]. The effect of quercetin on histamine release is unlikely to be due to inhibition of mitochondrial ATPase, as this should affect secretion induced by A23187 as well. It is also unlikely to be due to inhibition of the $(Na^+ + K^+)$ ATPase since ouabain even at 1 mM had no effect on the antigen-induced process. The secretory event involves Ca^{2+} movements, so it is most likely that the effect of quercetin on the abolition of secretion from ligand-stimulated cells is directed at the Ca^{2+} ATPase in the plasma membrane.

We therefore tested the flavones as inhibitors of rabbit sarcoplasmic reticulum Ca^{2+} ATPase (Table 1). It would be desirable to compare the inhibition of the mast cell secretory reaction with Ca^{2+} ATPase from the same source, but as it has been claimed[19] that the major Ca^{2+}-ATPase of the mast cell is reactive towards externally supplied ATP it is doubtful whether this enzyme is involved in Ca^{2+} transport. Even the association of this enzyme with the mast cell is open to doubt since the ecto-ATPase of 'purified' mast cell preparations is largely accounted for by the presence of contaminating macrophages[20]. We have therefore preferred to work with the Ca^{2+}-ATPase of sarcoplasmic reticulum which has a well-defined Ca^{2+} transport function. All of the compounds which inhibit mast cell histamine release also inhibit Ca^{2+} ATPase while morin and rutin are hardly inhibitory in either system.

Racker suggested that the transport ATPases of cell membranes and the associated ion flux pathways are separate structural entities, which when coupled together constitute the ATP dependent ion pumps[6]. In certain tumour cell lines the ion transport functions are apparently uncoupled from the ATPase functions[8] and to maintain the intracellular ionic milieu, ATP consumption rises. The consequent availability of ADP results in the characteristic enhancement of glycolysis and depressed *p*H (ref. 22) of some tumour tissues (Warburg effect). When treated with quercetin the efficiency of the transport ATPase is restored and the glycolytic rate declines[8] although quercetin is not an inhibitor of any of the glycolytic enzymes[23]. Quercetin also improved the Ca^{2+}-to-ATP ratio in reconstituted sarcoplasmic reticulum preparations[8].

Our results suggest that some flavones which affect the efficiency of membrane transport ATPases also prevent Ca^{2+} influx into ligand-stimulated mast cells, raising the possibility that the inhibitor is active at a common locus in both systems. We suggest that Ca^{2+} movements, that is, the efflux due to Ca^{2+} pumping, and influx which follows cross linking of surface receptors, share a common pathway. In the resting cell, the pathway is tightly coupled to the ATPase, but when the cells are treated with cross-linking ligands, the ATPase becomes uncoupled transiently from the flux pathway and there is a net movement of Ca^{2+} down its concentration gradient into the cell. Quercetin could prevent the ligand-induced uncoupling of the ATPase. The inhibitory effect of cyclic AMP on ligand-induced histamine release could also be exerted at the Ca^{2+} ATPase as cyclic AMP is known to modulate the effect of this enzyme[24].

We thank Mr Steve Young, who carried out the liposome Fe^{2+} efflux experiment, Drs Hare and Skidmore of Allen and Hanbury's Research Ltd for cyclic AMP phosphodiesterase measurements, and Dr Bob Hamill of the Eli Lilly Research Laboratories for ionophore A23187. This work was supported by the MRC.

Membrane defect affecting water permeability in human epilepsy

MCQUARRIE wrote that a disturbance in water balance perhaps affecting the central nervous system more specifically seems to be closely identified with the aetiology of epilepsy[1]. McQuarrie and Teglbjaerg[2] studied water balance in relation to seizure frequency, establishing the ictogenic effect of excessive water ingestion, and the therapeutic value of dehydration. Schneider[3] has reported that exacerbation of *petit mal* in children and adults is associated with reduction in urinary volume, and that clinical remission coincidences with an increase in water excretion. Reynolds[4] has demonstrated disturbances in the whole body distribution of water in epilepsy, with a magnitude proportional to the frequency of attacks, concluding that the changes in body water and sodium are linked in some way to the aetiology of the disease. Wender and Strzyzewski[5] have shown that water loading in epileptics produces seizures only in cases where there is also a marked increase in the water content of erythrocytes. There is thus abundant evidence linking epilepsy with water metabolism. Furthermore, diuretics, such as acetazolamid, are used in the therapy of epilepsies[6]. But the mechanism of the disturbance of water metabolism at the subcellular and molecular level has not been considered. We report here an investigation of water diffusion through erythrocyte membranes in epileptic children, made using a nuclear magnetic resonance (NMR) technique[7]. We found an abnormally low permeability in membranes from epileptics and suggest that a generalised membrane defect affecting water permeability is responsible for the disturbances of water metabolism in human epilepsy.

The NMR method has been applied to the study of water transfer across nerve cell membranes by Fritz and Swift[8]. The method involves addition of a paramagnetic solution ($MnCl_2$) to the plasma and measurement of the spin–spin relaxation time (T_2) of the erythrocyte water proton. The spin–spin relaxation time of water inside the isolated erythrocytes is about 140 ms and is much longer than the time required for water to penetrate the membrane (the water exchange time, T_{ae}), which is about 10 ms. If the relaxation time in plasma is made much shorter than the exchange time by adding the paramagnetic ion Mn^{2+}), the observed relaxation time of the erythrocyte (T_{2b}) is dominated by the exchange process through the membrane. T_{2b} is evaluated from a logarithmic plot of the nuclear spin echo as a function of the time between radiofrequency pulses[9]. T_{ae} is calculated as described by Conlon and Outhred[7]. The value of T_{ae} is inversely related to the water permeability of erythrocytes.

Table 1 Clinical features and therapy of epileptic patients

Mean ± s.e.m. 19.8 ± 2.2%.

The sample was made by mixing 1 ml of heparinised blood and 0.5 ml of 20 or 40 mM $MnCl_2$ solution in 0.15 M NaCl. NMR measurements were performed with a Bruker–Physik SXP spectrometer, at 90 MHz. The 90° pulse had a width of 5.5 µs. The spin–spin relaxation time was measured by the 90°*t* 180° method and the CPMG method with a pulse sequence spacing of 0.8 ms. Phase detection was used in both cases, and the field was stabilised with the BSN 15 external field stabiliser. The temperature unit of the spectrometer was adjusted to ± 0.5 °C. Measurements were made within several min of preparation of the sample. Blood samples from the epileptic and control children were handled simultaneously to assure comparable conditions. The results are expressed as percentage increase of the water exchange time (ΔT_{ae} %) in epileptic subjects, the reference being the normal blood. The reference values of T_{ae} for the normal blood were for the 90°*t* 180° method: 11.1 ms at 20 °C and 9.5 mM Mn^{2+} in plasma, and 8.2 ms at 37 °C and 19.5 mM Mn^{2+} in plasma. For the CPMG method T_{ae} = 8.7 ms at 37 °C and 19.5 mM Mn^{2+} in plasma.

Patients were 24 epileptic children aged 1–17 yr; their main clinical features are summarised in Table 1. An equal number of children aged 2–16 yr formed the control group.

Table 2 shows that in all epileptic children the exchange time of water through the red blood cell membranes was longer than in control subjects. The difference between T_{ae} in epileptic patients and controls was always positive, although measurements were made at different temperatures and concentrations of Mn^{2+}, and two methods were used to measure spin–spin relaxation time—the 90° *t* 180° method[7] and the Carr–Purcell–Meiboom–Gill (CPMG) method (which eliminates errors due to the inhomogeneity of the magnetic field and the molecular diffusion in field gradients[9]). It seems that the water permeability of erythrocyte membrane in epilepsy is less than in the normal situation. There were no significant differences in T_{ae} values between idiopathic and focal epileptics. High values of T_{ae} were noted in patients who suffered from attacks every day and in whom the attacks were poorly controlled by anticonvulsant drugs. But the value of T_{ae} during the attack was not higher than in the *interictal* period. This indicates that the low water permeability of erythrocytes in epilepsy is not transient but represents a permanent alteration. The abnormal water permeability was not related to the anticonvulsant therapy as it was noted in both untreated and treated patients.

Possible explanations for the observed difference in water proton transfer across the cell membranes in epileptics and normal subjects are an alteration of the erythrocyte permeability affecting water diffusion, and osmotic changes following the addition of the 0.15 M NaCl solution to the blood sample. Any osmotic changes would occur very quickly after mixture of the blood with the physiological saline solution. Consequently, such changes could not influence NMR measurements made several min after the blood was mixed with 0.15 M NaCl. Slow osmotic changes can be excluded because exchange time values remained unchanged for hours, both for normal subjects and epileptics. Alteration of erythrocyte permeability affecting water diffusion is thus the most likely explanation for our finding.

Abnormalities in functions of erythrocyte membranes are considered to indicate a generalised membrane defect[10,11]. Within certain limits a close qualitative and quantitative analogy is possible between the stability of the membrane of the erythrocyte and that of the neurone[12,13]. Fritz and Swift[8] have shown (by the NMR method we used) that for the frog nerve the exchange rate of the water protons between the intra- and extracellular environments is lower for the depolarised nerve than for the polarised nerve. That is, the water permeability of the membrane is smaller in the depolarised state than in the resting state.

The polarisation of the membrane is due to the differential distribution of Na and K across the excitable neuronal membranes, maintained by the Na–K-activated ATPase[14]. It has been suggested[15] that the final common expression of epileptogenicity is an impairment of operation of the Na and K transport systems in epileptogenic neurones, which creates the characteristic instability of the excitable membrane. Harris[16] has suggested that changes in distribution or transport of Na^+ and K^+ may not be due only to effects on the energy state or on ATPase activity, but may be a reflection of a generalised defect of membrane permeability.

We suggest that decreased water permeability in erythrocytes of epileptics may reflect a membrane defect in all tissues and may be an expression of the individual predisposition to epilepsy; it might be of particular importance in the nervous system. Further studies on erythrocyte membranes in epilepsy may give clues to the understanding of the membrane defect in molecular terms. The erythrocyte may be a useful model for testing *in vivo* the possible effectiveness of treatment with anticonvulsant drugs in individual patients, or for testing new anticonvulsant drugs.

We thank Drs Ileana Benga and Cornelia L. Morariu for helpful discussions and for blood samples.

New human embryonic antigen and its presence in some adenocarcinomas

IMMUNODIFFUSION methods have identified several embryonic antigens in tumour extracts or in sera of patients with primary cancer of the liver[1–3], colonic adenocarcinoma[4–6], testicular and ovarian teratoblastomas[7,8], carcinoma of the pancreas[9], chorionepithelioma of the uterus[10] and testicular chorioncarcinoma[11], nephroblastoma[12] and adenocarcinoma of the ovary[13,14]. We report here the use of monospecific antisera to identify a new embryonic antigen in human foetal sera and in some adenocarcinoma extracts.

Antisera against extracts of human ovarian adenocarcinomas were prepared in rabbits[13]. After absorbtion by human pooled plasma (20–40 mg ml^{-1}) and pooled extracts

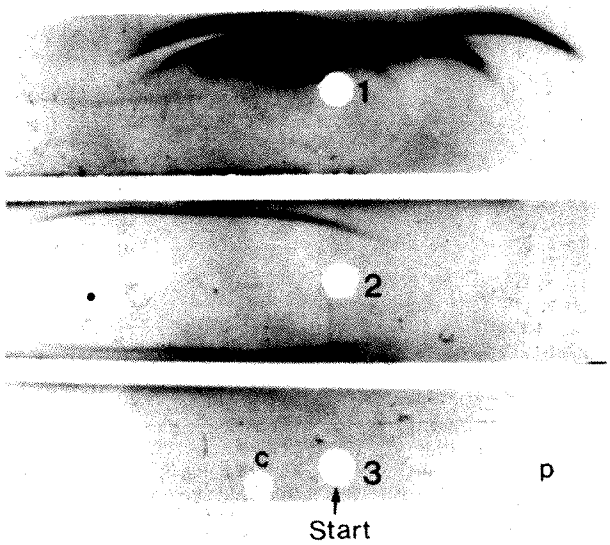

Fig. 1 Gel immunoelectrophoresis of human foetal and adult sera. Precipitation lines were developed with antiserum against human serum proteins[4] and with adsorbed antiserum against ovarian adenocarcinoma extract[2]. Sera of: 1,3, human pregnancy sera; 2, foetus of 20 weeks. Zone of migration: c, colour T-1824; p, pyronine.

Table 1 Immunodiffusion of absorbed antisera against various sera and tissue homogenates

Sample	No. of samples examined	Results of gel diffusion analysis No. positive	No. negative	Titre
Human serum of				
Foetuses of 20–30 wk	20	20	0	1:8–1:32
Foetuses of 30–40 wk	11	11	0	1:2–1:8
Newborns of 30–40 wk	20	20	0	1:1–1:2
Adult donors (male and female)	50	0	50	—
Tissue homogenates of				
Ovarian adenocarcinoma	26	13	13	1:1
Colonic adenocarcinoma	17	7	10	1:1
Carcinoma of stomach	16	3	13	1:1
Uterine carcinomas	9	0	9	—
Lung carcinoma	5	0	5	—
Miscellaneous	10	0	10	—
Normal adult, various organs*	36	0	36	—

*Included ovary, testis, liver, spleen, pancreas, kidney, gastrointestinal tract, brain and muscle tissue.

of normal tissues (40–60 mg ml^{-1}) the antisera were used for immunoelectrophoresis[15] and immunodiffusion in agar[16]. The newly discovered antigen migrated with α-globulin and prealbumin in immunoelectrophoresis (Fig. 1). Similar electrophoretic fractions are present in all human embryonic sera. Immunodiffusion analysis revealed analogous antigen in sera of newborns as well as in some individual extracts of ovarian and colonic adenocarcinomas (Fig. 2) but not in adult sera or in other normal and malignant tissues. These data are summarised in Table 1.

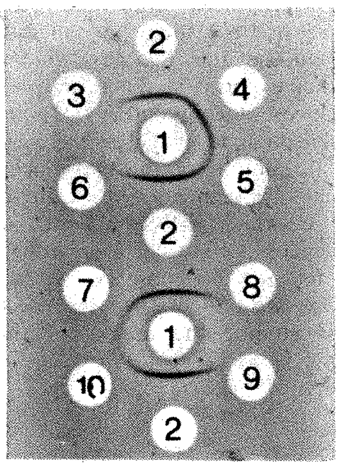

Fig. 2 Gel double diffusion with standard test system: 1, monospecific antiserum; 2, standard antigen. Human serum of 3, adult donor: 4, foetus 20 weeks; 7, newborn. Homogenates of 5,6, ovarian adenocarcinomas; 8, hypernephroid tumours; 9,10, colon carcinomas.

Comparative immunodiffusion showed that the reported embryonic antigen was not identical to α-foetoprotein[17], carcinoembryonic antigen[4], bovine fetuin[18], or pregnancy-specific β-1-globulin[10].

The results suggest that the newly identified antigen is a serum protein secreted during embryonic development, and can be synthesised in adults with adenocarcinomas. The physiological role and cellular localisation of this antigen are not known.

Reconstitution in phospholipid vesicles of a glucose transport system from pig small intestine

Absorption of monosaccharides from the small intestine in mammals occurs by several different processes. The major barrier to absorption is the brush border membrane of the epithelial cells across which glucose is transported against its concentration gradient in a sodium-coupled transport system. We describe here some properties of monosaccharide transport from phospholipid vesicles into which brush border proteins obtained from neonatal pig small intestine were incorporated. The system transported glucose, but not fructose more rapidly in the presence of a sodium gradient; it transported D-glucose more rapidly than L-glucose and efflux was reduced by phlorizin.

Small intestines were removed from unfed newborn pigs from the Babraham herd. All biochemical procedures were performed in a cold room at 5 °C. Preparations of small intestinal brush border membranes were made by a modification of the method of Porteous[1]; purity was checked by phase-contrast microscopy. There was no reaction to the diphenylamine reagent test for DNA in brush-border samples. Table 1 shows the results of enzymatic assays on subcellular fractions. Although there was little mitochondrial contamination there was evidence of acid phosphatase release from lysosomes. The preparation contained some baso-lateral membranes. Brush border proteins were either immediately incorporated into phospholipid vesicles, or stored deep frozen for up to 2 months before use, with small loss in glucose-transporting activity.

Phospholipid vesicles were prepared from purified soya bean phospholipids using cholic acid, the modification by

Table 1 Enzymatic activities in small intestines of newborn pigs

Enzyme	Crude homogenate	Mitochondrial fraction	Brush-border fraction
Monoamine oxidase[2] (nmol tyramine oxidised h^{-1} mg protein^{-1})	200.9	318.6	189.2

Acid phosphatase[4] (μmol *p*-nitrophenylphosphate metabolised h^{-1} mg protein^{-1})	212.8	976.2	1872.2
Sucrase[5] (μmol metabolised h^{-1} mg protein^{-1})	—	—	< 50

Warren *et al.*[6] of Racker's[7] method. Vesicles containing brush border protein were prepared in sodium–sucrose buffer (*p*H 8.0) containing 250 mM sucrose, 1 M NaCl, 50 mM NaH_2PO_4 and 2 mM glucose, or in other experiments, appropriate monosaccharide mixtures or phlorizin. Cholic acid was dialysed away overnight against the same buffer at *p*H 7.2. The sugar was labelled by allowing exchange with an appropriately labelled radioactive sugar in the medium for at least 30 min before each experiment. Initial experiments established the optimum ratio of phospholipid : cholic acid : brush border protein in the mixture before formation of the vesicles, as 60 : 30 : 1, a proportion similar to that used by Warren *et al.*[6]. Transport of sugars from the vesicles was measured by holding them within the cellulose hollow fibres of a Bio-Rad Bio-Fiber Mini-beaker. These fibres allow compounds of molecular weight < 5000 to diffuse freely into the fluid which was pumped through the beaker at a constant rate of 4.5 ml min^{-1}. Aliquots of perfusate were collected with a fraction collector and radioactivity measured by liquid scintillation spectrometry. The fluid used to perfuse the fibres was either of the same composition as the fluid against which the vesicles were dialysed (though containing neither glucose nor fructose) or a potassium–sucrose buffer containing identical amounts of equivalent potassium salts. Normally each perfusion involved an initial period during which sodium–sucrose buffer was perfused through the beaker and collected, and a second period of perfusion with potassium–sucrose buffer. Radioactive glucose or fructose released from the hollow fibres during the first period was from two sources—extravesicular fluid, and from inside the vesicles flowing down a concentration gradient. In the second period, amounts of monosaccharide from these first two sources were small, the majority being released from the vesicles when there is a sodium gradient from within the vesicles to the bathing fluid.

Figure 1 compares the release of glucose in vesicles containing brush border protein with those without protein. In Fig. 2 the outflow of glucose is seen in the absence of a sodium gradient together with the relative outflows of D- and L-glucose in the presence of a sodium gradient, D-glucose being transported more readily than its isomer. Total glucose release measured in tubes 40–60 inclusive was 3.11 μg D-glucose and 1.95 μg L-glucose (ratio D : L, 1.59). In a further experiment the release of D-glucose was 5.02 μg and L-glucose 4.07 μg (ratio 1.23). In both of these experiments phospholipid vesicles were loaded with a mixture of equal amounts of the two glucose isomers and the simultaneous release measured. A further experiment was performed in which half of a batch of vesicles was loaded with D-glucose, the other half with L-glucose;, here 10.66 μg and 6.67 μg L-glucose were released by the application of the sodium gradient (ratio 1.60).

Murer *et al.*[8] studied the uptake of the two glucose

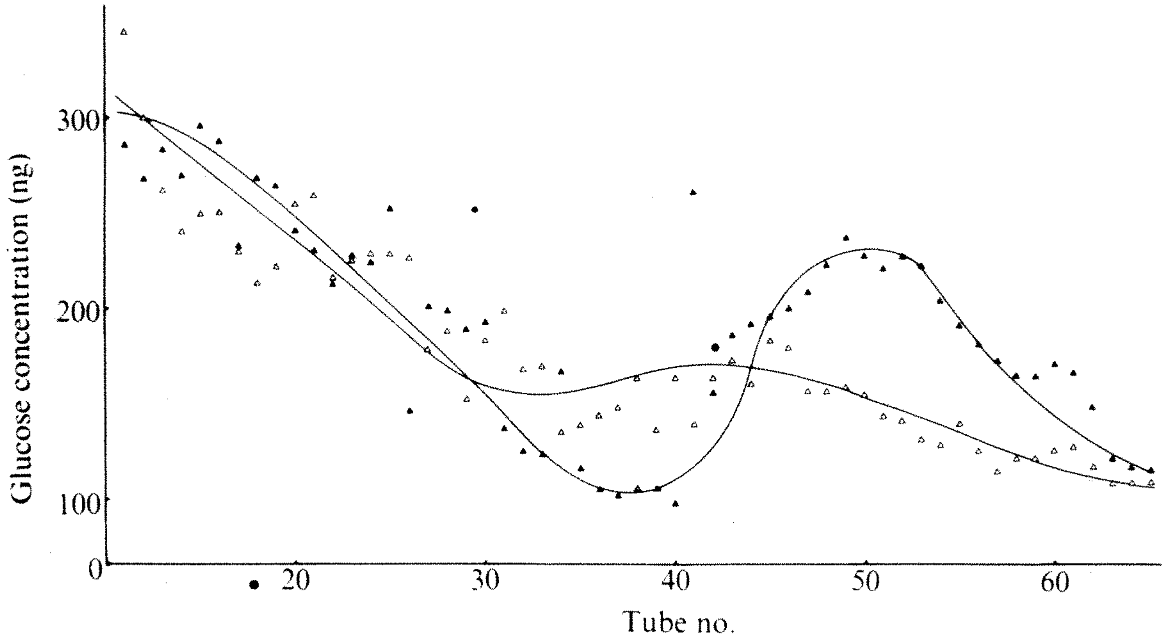

Fig. 1 Glucose release from phospholipid vesicles containing brush border protein (▲) and containing no protein ( ). The sodium gradient was introduced at tube 30 by perfusion with potassium–sucrose buffer. The delay in appearance of glucose from the vesicles containing protein is due to the deadspace in the system. Total glucose released from the protein-containing vesicles between tubes 40 and 60 was 4.03 μg, from those without protein 3.02 μg.

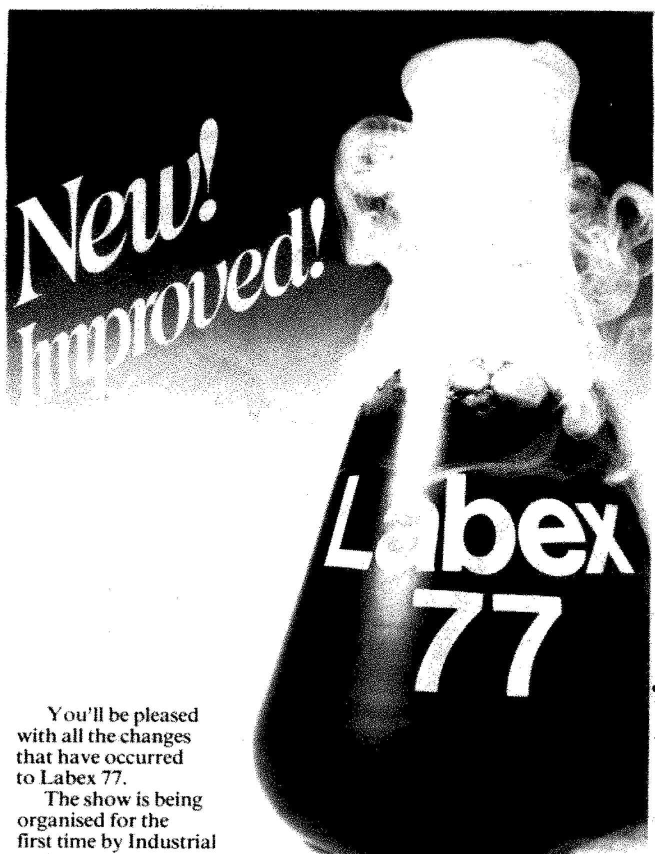

New!
Improved!
Labex
77

You'll be pleased with all the changes that have occurred to Labex 77.

The show is being organised for the first time by Industrial and Trade Fairs Limited, (the world's largest independent exhibition organiser), by arrangement with U.T.P. Exhibitions Ltd.

The scope of the show is wider, the facilities are better at the National Exhibition Centre, Birmingham.

Come to the new, improved Labex 77. Compare. Discover new products. Establish new sources of supply. You'll be glad you did.

If you're coming by rail the Centre's new Birmingham International station is only 80 minutes from London's Euston by fast Inter-City express. The NEC is just off the motorway with parking for over 10,000 cars, if you come by road. The airport's just across the way, too.

You can also attend the Labex lecture on Tuesday 8th March. Sir Bernard Lovell will speak on 'Measurement of the Universe' at the Metropole Hotel alongside the Centre.

Resolve to come to Labex 77 send for your registration cards NOW!

When you're studying cyclic nucleotides and you don't know which way to turn

We understand that when you are working in the cyclic nucleotide area, the subject is so diverse and so complex that you don't want to have to worry about the problems of accurate measurement.

So we would like to take a little weight off your mind and offer you our two kits in this field.

Cyclic AMP and Cyclic GMP.

Both of the tests are simple, accurate and will take you about four hours from start to finish.

So it's not surprising that you can carry on with your research and leave the problems of accurate measurement to us.

You know where you are with our Cyclic AMP & GMP kits

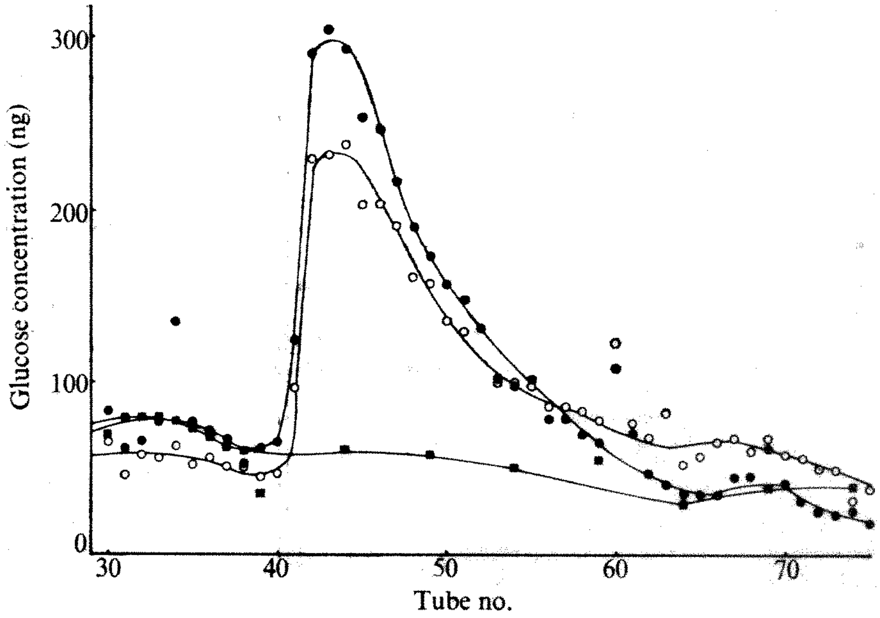
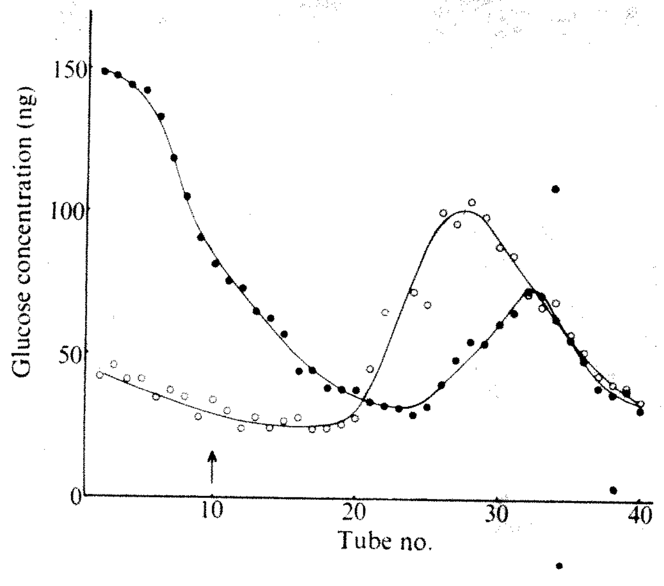
Fig. 2 Glucose release from phospholipid vesicles; *a*, in the absence of a sodium gradient (■); *b*, after loading with a mixture of D- and L-glucose, D-glucose being labelled with ^{3}H(●) and L-glucose with ^{14}C(○). The sodium gradient was introduced at tube 30.



isomers into isolated brush border vesicles using a filtration method; although after 120 s D-glucose uptake was 3.3 times greater than L-glucose, the ratio after 25 min was 1.4, similar to that seen in the present experiments.

Phlorizin (which inhibits transport of glucose both in small intestine and the renal proximal tubule) was incorporated into phospholipid vesicles at 5×10^{-4} M together with 2 mM glucose, and efflux of glucose was compared with controls containing no phlorizin (Fig. 3.) The initial loss of glucose from the vesicles down its chemical gradient was higher in the control than in the presence of phlorizin. After application of the sodium gradient, 0.84 μg of glucose was lost from the controls and 1.26 μg from the vesicles with phlorizin, the greater loss from the latter experiment probably being due to the larger amount of glucose which was still present in those vesicles. Total loss of glucose from control vesicles during the complete experiment was 2.7 μg, and in the presence of phlorizin, 1.9 μg. Fructose is not absorbed from the intestine by a sodium dependent mechanism, so the efflux of this sugar was compared with that of glucose. Vesicles were loaded with a mixture of ^{3}H-glucose 1.5 mM and ^{14}C-fructose 1.5 mM. Three perfusions were performed and the amounts of glucose released during the peak after the addition of the sodium gradient were 5.6, 5.1 and 5.14 μg, and of fructose, 2.11, 0.89 and 2.79 μg respectively. Furthermore, there was no significant rise in fructose efflux when the sodium gradient was introduced (Fig. 4).

Fig. 3 Release of D-glucose from phospholipid vesicles; *a*, control (●) and *b*, in presence of 5×10^{-4} M phlorizin (○). Vesicles were perfused with sodium sucrose buffer from samples 1–10. At the arrow it was changed to potassium–sucrose buffer. As in Figs 1 and 2 peaks show glucose release in response to the production of a Na$^+$ gradient.



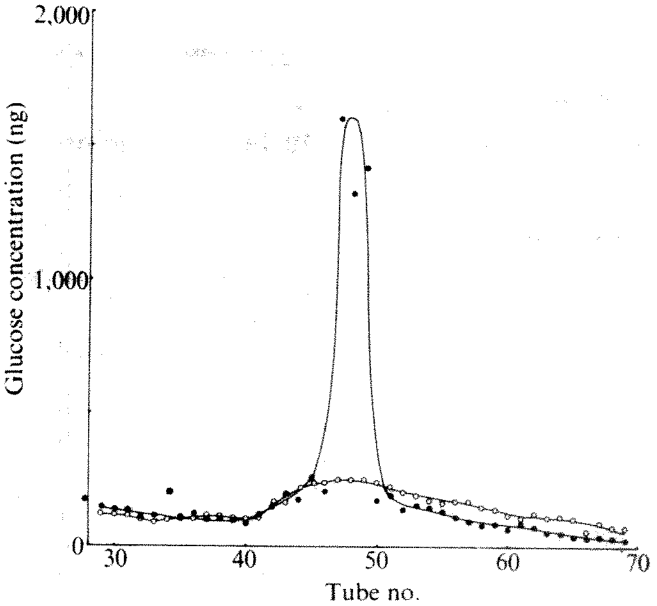


Fig. 4 Release of D-glucose (●) and fructose (○) from phospholipid vesicles in the presence of a sodium gradient introduced at tube 30.

The results of experiments using L-glucose and fructose might be explained if exchange of the labelled compounds with unlabelled sugar in the vesicles was not complete at 30 min. This is unlikely for three reasons. First, there was no change in the relative efflux of the two compounds when vesicles had been in contact with the isotope for varying times in excess of the initial 30 min. Second, the initial period, which consists at least in part of sugar from inside the vesicles, was very similar in D-glucose, L-glucose and fructose-loaded vesicles. Third, after the large sodium-dependent efflux of D-glucose the depleted vesicles released less than the vesicles containing a sugar, for example, L-glucose more resistant to release by a sodium gradient, so that in Fig. 1 the efflux of D-glucose crosses that of L-glucose after the peak efflux has occurred, and this was a consistent finding.

Our results show that a glucose transporting system can be reconstituted from phospholipid vesicles and protein from brush border membranes from small intestinal cell brush borders from pigs. This transport resembles the characteristics of transport of glucose in intact tissue in that it is increased in the presence of a sodium gradient, whereas the transport of a closely related sugar, fructose, is not. Furthermore, the reconstituted system distinguishes D-glucose from the L-isomer, and the total efflux of glucose is also reduced by phlorizin.

We thank Dr M. W. Smith for advice and assistance.

Immunofluorescence shows localisation of prolactin to human amnion

AMNIOTIC fluid in man and rhesus monkey contains very high concentrations of prolactin[1–3], but its origins are unknown. It does not seem to come from the maternal circulation because isotopically labelled prolactin injected into the pregnant rhesus monkey does not appear in amniotic fluid[2]. One source of prolactin is suggested by the passage of foetal pituitary prolactin through the immature kidney into the urine and then into amniotic fluid[4,5]. But amniotic fluid and foetal prolactin differ in molecular size, suggesting different origins[4]. Incubated human amnion and chorion, but not placenta, release prolactin into the medium, indicating a second source of amniotic fluid prolactin[2]. Using indirect immunofluorescence, we report localisation of prolactin to the human amnion.

Placentae and amniotic membranes were collected from normal pregnancies of 12–40 weeks gestation, which had been terminated for psychiatric reasons in the second trimester by hysterotomy or had been delivered vaginally either prematurely or at term in the third trimester. The tissue was immediately cooled in ice and rinsed clean of blood and amniotic fluid with phosphate-buffered saline (*p*H 7.4). Within 90 min of delivery, tissue blocks (1 cm^3) of cotyledon, umbilical cord, placental and reflected parts of the amnion and the chorion laeve were snap frozen in isopentane liquid nitrogen at −70 °C. Specimens were also fixed in 10% phosphate-buffered formalin for conventional histology.

Frozen sections, 6 μm thick, were cut on a Lipshaw cryostat and examined by indirect immunofluorescence[6] using rabbit antisera to human prolactin obtained from the National Institutes of Health, Bethesda, Maryland. The reaction was traced with a fluorescein isothiocyanate-labelled goat anti-rabbit γ-globulin. The unabsorbed conjugate had a fluorescein to protein molar ratio of 4.8 : 1 and was absorbed with rat liver, kidney, gastrointestinal tract, sheep liver and human placenta so that it gave no nonspecific staining. The absorbed conjugate was used at a protein concentration of 8 mg ml^{-1}. After staining, the sections were examined by dark ground ultraviolet fluorescent microscopy using a condenser fitted with a colourless barrier filter and a toric lens beneath.

Immunological specificity of the reaction was assessed by reacting parallel control sections with conjugate alone, normal rabbit serum or rabbit anti-human prolactin neutralised by absorption with human prolactin, growth hormone or chorionic somatomammotrophin (placental lactogen). For neutralisation studies, 50 μl of rabbit anti-human prolactin was incubated overnight with 100 μl of human prolactin at a concentration of 6 μg ml^{-1}. The other hormones were used at similar concentrations. The rabbit anti-human prolactin serum was examined in a radioimmunoassay, and did not bind human growth hormone, insulin, chorionic somatomammotrophin or gonadotrophin, pituitary thyrotrophin and gonadotrophins or prostaglandins $F_2\alpha$ or E_1.

Multiple sections from seven pregnancies stained with rabbit anti-human prolactin showed specific immunofluorescence localised to the cytoplasm of the amnionic epithelium. Figure 1 demonstrates the uniform staining reaction throughout the cytoplasm of all epithelial cells. The intensity of immunofluorescence varied with the amnion of different patients and in general was more intense in the second trimester, but there seemed to be little variation in staining reaction between the placental and the reflected amnion from the same patient. In some sections, occasional blood vessels deep to the amnionic epithelium showed positive staining but this was never as intense as the staining of the overlying epithelium. No immunofluorescence was observed in the chorion laeve, umbilical cord or placental chorionic villi. Control section of amnion failed to stain when tested with conjugate alone or with normal rabbit serum. Antiserum absorbed with growth hormone or chorionic somatomammotrophin stained the amnionic epithelium but antiserum absorbed with human prolactin did not stain.

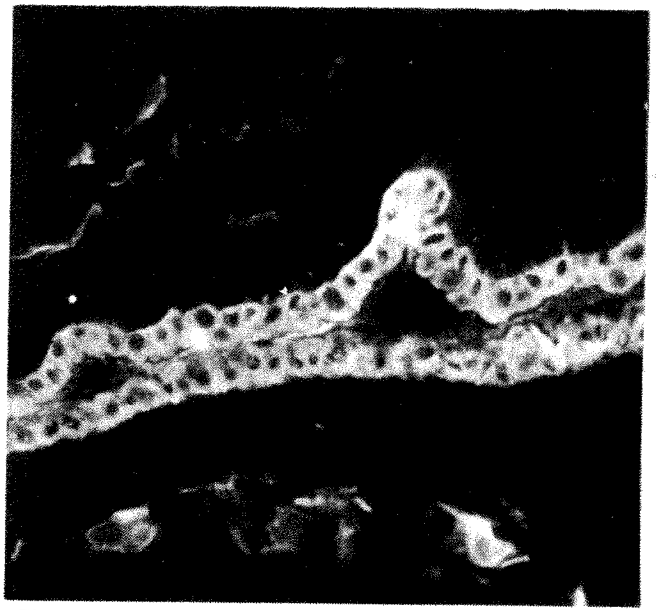

Fig. 1 Cytoplasmic immunofluorescence of a fold of human amnion epithelium from a 28-week pregnancy stained by rabbit anti-human prolactin. Small blood vessels are also stained (× 572).

We have demonstrated that prolactin is localised in the cytoplasm of human amnionic epithelium. It is possible that prolactin synthesis occurs in these cells, thus contributing to the relatively high concentrations of prolactin in amniotic fluid. The amnion epithelial cells are metabolically active[7] and contain rough endoplasmic reticulum capable of protein synthesis[8,9]. Although prolactin receptors have not been reported in human placental membranes or myometrium, this hormone influences water and electrolyte change in many species including man and may affect the volume and composition of human amniotic fluid[10–12]; in addition, it inhibits myometrial contraction[13]. Local production or concentration of prolactin by the epithelial cells of the amnion would facilitate these functions.

Palatal cytosol cortisol-binding protein associated with cleft palate susceptibility and *H–2* genotype

GENETICALLY different inbred strains of mice have different susceptibilities to the production of cleft palate by a standard dose regimen of corticoids at the critical period during palatal organogenesis[1]. Because in target tissues corticoids form a specific cytoplasmic cortisol–receptor complex which interacts with the genome, resulting in activation or depression of transcription[2,3], we have postulated that susceptibility to corticoid-induced cleft palate is mediated by genetic differences in a cytosolic corticoid receptor protein(s) in palatal anlagen[4]. Other studies have suggested that susceptibility to cortisone-induced cleft palate is regulated by genes closely linked to the *H–2* locus[5]. We report here that the total level of cytosolic protein binders of ^{3}H-cortisol in maternal and foetal palates on day 11 of gestation correlates with susceptibility to cleft palate and with the *H–2* genotype. After separation of macromolecular bound hormone from free hormone on columns of Sephadex G-25 and further separation by microelectrofocusing[6], only one maternal and foetal palatal cytosol binder for ^{3}H-cortisol (pI 6.9–7.0) was found to correlate with susceptibility to cleft palate and the *H–2* genotype. Thus, a product of a gene in or near the *H–2* locus seems to be the glucocorticoid receptor, the level of which must be increased for a congenital malformation to occur.

The percentages of offspring in the different strains with cleft palate after maternal administration of corticoids were A/J, 100, DBA/1J, 92; C3H/HEJ, 68; C57BL/6J, 19 and CBA/J, 12, respectively[1]. This production of cleft palate by corticoids has been associated with the *H–2* genotype by the observation that the incidence of cortisone-induced cleft palate in C57BL/10 ScSn (B10) is 21%, and that of A/J is 100%, whereas that of B10.A, which has the genetic background of B10, but the *H–2*^{a} allele of A/J, is 81% (ref. 5). Foetuses of the sensitive A/J strain retain more ^{14}C-cortisone during the critical period than do those of the resistant strains, CBA/J (ref. 7) or C57BL/6J (ref. 8). Furthermore, synthetic corticoids are recovered in the unmetabolised state from foetal A/J tissues[10] and inhibit foetal RNA and protein synthesis at the critical period of cleft palate production[11]. A/J foetuses are more sensitive to an inhibition of RNA synthesis than those of the C3H/HEJ strain[12] and the effect is not due to a difference in metabolism of the steroid by A/J and C3H/HEJ strains[10].

A typical microelectrofocused pattern of ^{3}H-cortisol-binding proteins in the foetal jaws of each of the five inbred strains is shown in Fig. 1. Only one ^{3}H-cortisol-binding protein increased in amount in the different strains in proportion to the reported incidence of cleft palate produced by the standard cortisone regimen (indicated by arrows) (Fig. 1).

Most of the ^{3}H tightly bound to protein in the cytosol and nuclei of the foetal jaws was unmetabolised ^{3}H-cortisol (Fig. 2).

A linear regression analysis of each peak microelectrofocused showed a highly significant correlation between the amount of ^{3}H-cortisol-binding protein and the reported incidence of cleft palate in the seven strains: there was only one peak (pI 6.9–7.0) in both maternal palates ($r = 0.485$, $n = 27$; $P < 0.015$) and foetal jaws ($r = 0.585$, $n = 19$; $P < 0.016$) (Fig. 3).

A linear regression analysis also demonstrated that the total ^{3}H-cortisol-binding proteins in maternal ($r = 0.412$, $n = 30$, $P < 0.025$) and foetal ($r = 0.494$, $n = 18$, $P < 0.042$) palates of each of the seven strains was significantly correlated with the reported incidence of corticoid-induced cleft palate in that strain (data not shown). Moreover, when a pool of five adult male palates each of the B10 and B10.A strains taken 1 h after injection of 10 μCi ^{3}H-cortisol was analysed for this ^{3}H-cortisol-binding protein, the values plotted on the same linear regression curve as the maternal palates of the seven strains.

Our results show that the levels of foetal and maternal palatal cytosolic ^{3}H-cortisol-binding proteins (total and pI 6.9–7.0) are correlated with susceptibility to corticoid-induced cleft palate and are associated with alleles at the *H–2* locus. The *H–2* locus is not the sole determinant of ^{3}H-cortisol receptor levels, for C3H/HEJ (*H–2*^{k}) and CBA/J (*H–2*^{k}) have the same *H–2* genotype but different cleft palate susceptibilities and receptor levels. Our data suggest, however, that the ^{3}H-cortisol-binding protein with pI 6.9–7.0 is a candidate for the cortisol receptor in the mouse palate and that susceptibility to cortisol-induced cleft palate is mediated by this candidate for the cortisol receptor. A similar mechanism has been invoked to explain why medroxyprogesterone acetate produces cleft palate in

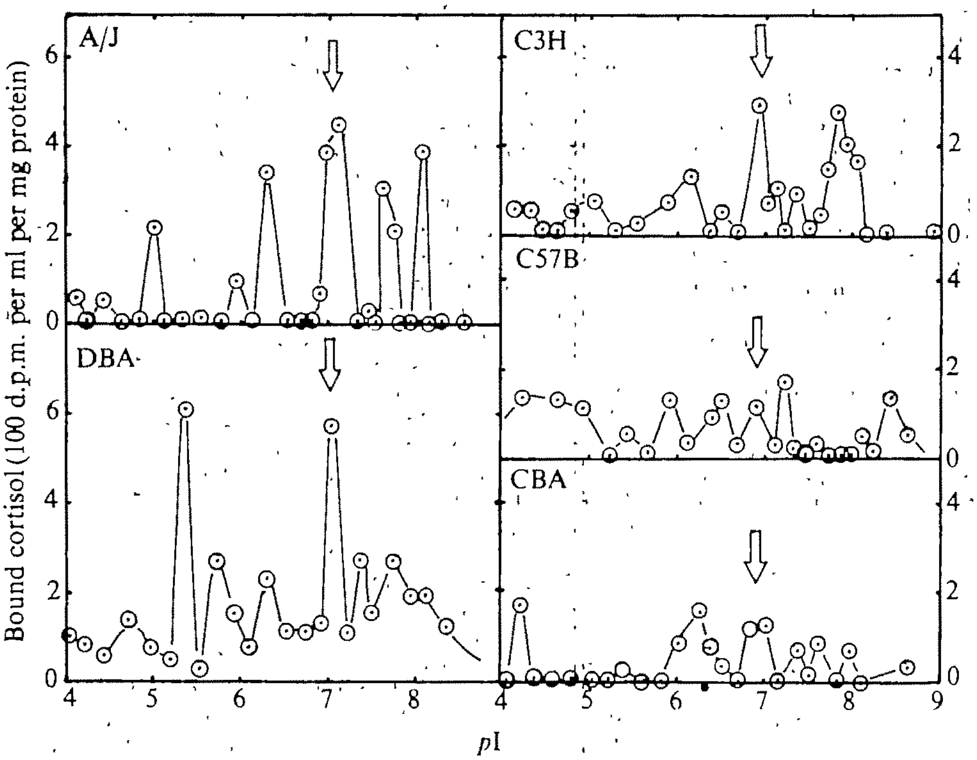

Fig. 1 Typical microelectrofocusing pattern of 1,2,6,7-^{3}H-cortisol-binding proteins in cytosol of foetal jaws after gel filtration through Sephadex G-25 Pregnant mice were killed by decapitation at 11 d of gestation (day of vaginal plug = day 0) 1 h after subcutaneous injection of 5 μCi of 1,2,6,7-^{3}H-cortisol (90 Ci mmol^{-1}). Maternal palates and the jaw regions (horizontal cut of the foetal head just below the level of the eyes including upper and lower jaws) of foetuses obtained by caesarian section were dissected, pooled (two or three maternal palates per pool and jaws of all foetuses in one or two litters per pool) and homogenised in a fivefold volume of 0.3 M sucrose–1 mM EDTA–20 mM Tris–50 mM phosphate buffer, pH 7.4 Cytosol was prepared, filtered through Sephadex G-25 and microelectrofocused as described before[6] with the exception that the columns were changed to 25-ml pipette and the Triton X-100 was eliminated. Each 0 5-ml sample was fractionated after electrofocusing at 200 V for 40 h. Radioactive samples were mixed with Formula 950A (New England Nuclear) and counted in a Packard Tricarb model 3375 scintillation spectrometer with a counting efficiency of 30–40% for ^{3}H Quenching was determined by an automatic external Standardisation ratio method. Protein was determined by the method of Lowry *et al.*[17]. The arrows indicate the *p*I 6 9–7.0 binding protein The amount of this protein is proportional to the reported incidence of cleft palate produced by four daily doses of 2.5 mg cortisone from days 11 to 14 of gestation in the different strains (Fig. 3). Each determination represents a pool of all the foetal jaws in one or two litters.

rabbits, but not in rats, since medroxyprogesterone acetate effectively competed with the binding ^{3}H-dexamethasone to the rabbit, but not to the rat liver glucocorticoid receptor[9].

We have found ^{3}H-cortisol largely in the unmetabolised state in the nuclei of the foetal jaws 1 h after maternal injection. This suggests nuclear uptake of a cortisol receptor, which presumably then results in repression or derepression of protein synthesis.

Detailed purification efforts reported so far by two groups have shown that the major rat[13,14], guinea pig[15] and human[16] liver glucocorticosteroid receptor capable of nuclear transfer *in vivo* and *in vitro* has an isoelectric point of either 7.1 and 6.1 after thermal activation[16], or 6.7 (refs 11–13). Other binding fractions found by us and the other groups do not seem to be receptors but transcortin (corticoid-binding globulin), ligandin (possibly an enzyme) or receptor fragments. The similarity of the *p*I of the ^{3}H-cortisol-binding protein associated with susceptibility to cleft palate with those of the liver glucocorticoid receptor found by the two groups makes the protein a candidate for a palatal glucocorticoid receptor mediating cleft palate.

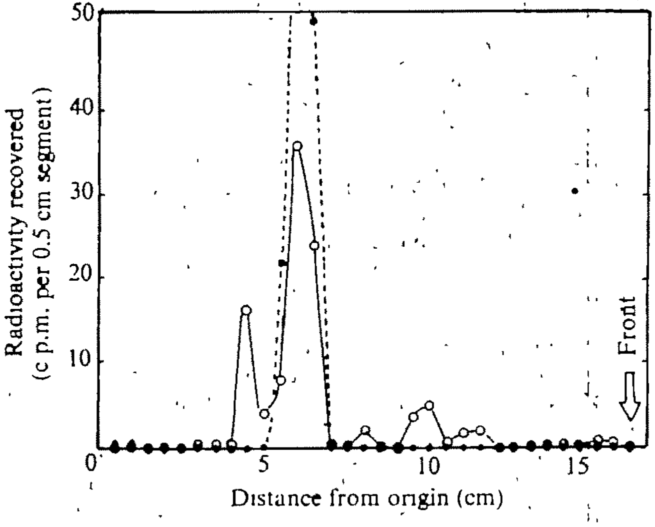

Fig. 2 From 75 to 80% of the ^{3}H in a 50% methylene chloride–chloroform extract of the cytosol and nuclei of the foetal jaws of the sensitive strains cochromatographed with an equivalent amount of ^{14}C-cortisol in a thin-layer chromatogram developed in cyclohexane–ethyl acetate–ethanol (45:45:10, v/v/v). The remainder of the ^{3}H was not identified accurately, but had the same mobility in this system as a non-radioactive cortisol metabolite, 3β, 11β-17α-, 21-tetrahydroxy-5α-pregnane. Circle and dot, ^{3}H in extract; ●, authentic ^{14}C-cortisol.

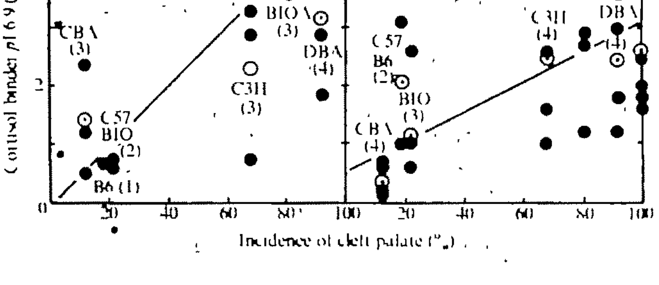

Fig. 3 Linear regression analysis of *p*I 6.9–7 0 receptor level of foetal jaws (*a*) and maternal palates (*b*) for each strain compared with reported mean incidence of cleft palate in each strain. The numbers in parentheses indicate the number of pools of adult palates or foetal jaws Circle and dot, mean value of all pools for each strain; ●, value of each pool.

The association between H–2 genotype and level of cortisol receptor in the cytosol suggests that the protein with pI 6.9–7.0 is either coded by a gene closely linked to the H–2 region or coded elsewhere in the genome, but is strongly affected by a gene in or near the H–2 region. Thus, the diversity of effects known to be associated with H–2 could be explained by a series of closely linked genes adapted to serve either immunological or hormonal functions.

After submission of our paper evidence in agreement with our findings was reported, to the effect that foetal A/J facial mesenchyme cells contain about twice the amount of saturable dexamethasone receptors than C57BL/6J mesenchyme cells obtained either directly or in primary culture[18].

Neuroanatomical focus for morphine and enkaphalin-induced hypermotility

OPIATE receptors, through which all opiate alkaloids and peptides produce their pharmacological effects, are distributed heterogeneously in the mammalian brain[1–3]. The highest receptor densities seem to be associated with a number of limbic midbrain and forebrain structures that have been implicated in regulating motivation and emotionality[5,6]. Although the limbic midbrain region (periventricular-periaqueductal grey matter) is a critical focus for the analgesic[4–7] and depressant (A.P. and C.S., in preparation) effects of morphine and enkephalin[8], nothing is known about the functional significance of opiate receptors in the forebrain. Significantly, the nucleus accumbens (NA) in the limbic forebrain contains a relatively high concentration of opiate receptors[4] (C. B. Pert, personal communication). As this structure has a role in motility[9,10], an attempt has been made to ascertain whether it is an important focus for the excitatory effects[11,12] of opiates on behaviour. We report here that direct injections of morphine, D-Ala^2-enkephalin-amide (an enzyme-resistant enkephalin)[7,13] and apomorphine (a dopamine agonist) into the nucleus accumbens increased spontaneous motor activity in rats. The excitatory effects of morphine were antagonised by naloxone (an opiate antagonist) and not by haloperidol (a dopaminergic antagonist). Conversely, apomorphine was antagonised by haloperidol and not by naloxone.

Thirty-five male Sprague–Dawley rats, anaesthetised with sodium pentobarbital, were implanted stereotactically with bilateral intracerebral cannulae guides constructed from 23-gauge hypodermic tubing. The guide cannulae tips were aimed for a region 2 mm dorsal to the NA (AP 9.4, LAT 1.5, DV 2.0) (ref. 15). Drugs were injected into the NA through 30-gauge injectors which protruded 2 mm past the guide tips. Drug and control solutions were administered in a volume of 1 µl and at a rate of 1 µl per 30 s. One group of 10 animals was injected bilaterally in the NA with 5 µg morphine sulphate (that is, a 10 µg total dose), 10 µg apomorphine and 1 µl of water (the drug vehicle). All animals received both drugs and the vehicle in a counterbalanced order separated by 7 d. Another group of animals (n=9) was injected in the NA with both 10 µg D-Ala^2-enkephalin and 1 µl of water in a counterbalanced order, as above. Immediately after injections the animals were placed in Plexiglas chambers (23×23×15 cm) which were mounted in Motron motility meters (model 40Fc). Horizontal and vertical activity was monitored in 30-min segments for 6 h. Animals in these studies were always injected at 1000 h and removed from the apparatus at 1600 h. Six additional rats received injections of morphine and the vehicle into a region 2 mm dorsolateral to the NA. These rats were tested 30, 180 and 360 min after injection for 30 min.

Other groups of rats were injected with either 10 µg of apomorphine or 5 µg of morphine in the NA. Rats injected with apomorphine were pretreated with either naloxone (10 mg per kg body weight), haloperidol (0.25 mg per kg body weight) or normal saline administered intraperitoneally (i.p.) 15 min before being injected intracerebrally (i.c.). Rats injected with morphine i.c. were injected i.p. with either haloperidol, naloxone or normal saline 165 min later. Rats injected i.c. with morphine were placed in the apparatus 180 min after the i.c. injection. Rats injected with apomorphine were tested immediately after injection. These regimens were adopted to assure that both i.c. drug effects were at asymptotic levels during testing. All animals were tested for 30 min. Two groups of rats were also tested 15 min after i.p. injections of either naloxone and saline or apomorphine and saline. Rats in the above studies were tested between 0900 and 1500 h.

Apomorphine produced an immediate increase in both horizontal and vertical spontaneous activity after NA injections. This hyperactivity dissipated rapidly over 1 h and was no longer detectable 90 min after injection. Morphine, however, induced a more gradual increase in activity which reached asymptotic levels in approximately 3 h and was still present 5.5–6 h after injection. The excitatory effect of D-Ala^2-Met-enkephalin also had a gradual onset but was not as persistent as morphine (Fig 1).

Naloxone pretreatment antagonised the excitatory effects of morphine, whereas haloperidol was ineffective. Apomorphine, on the other hand, was antagonised by haloperidol and not by naloxone. Both naloxone and haloperidol decreased motor activity at the doses tested. Only the

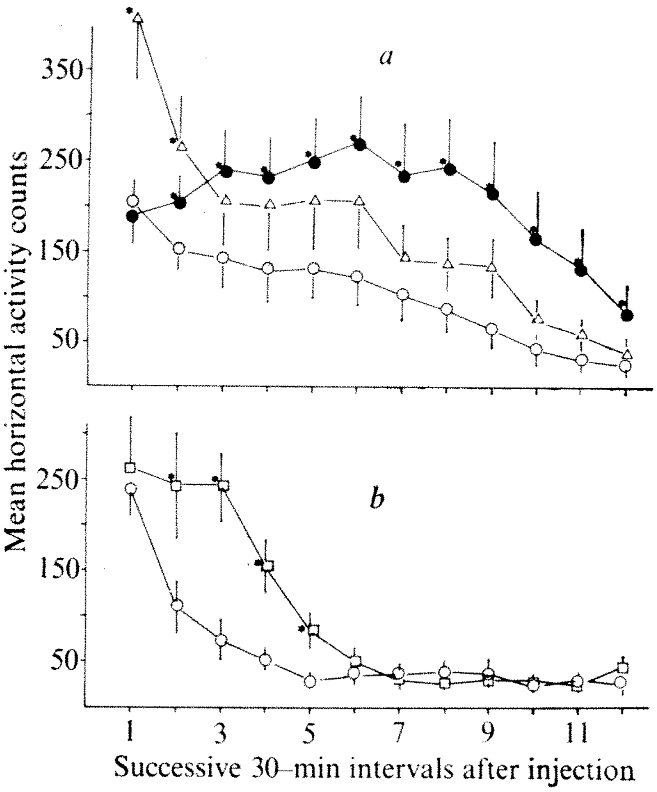

Fig. 1 Time course of horizontal hypermotility after bilateral injections of vehicle alone (○), morphine 5 µg (●), apomorphine 10 µg (▲) or D-Ala²-Metenkephalin 10 µg (□) into the NA. Repeated measures analyses of variance revealed a significant drug effect for both groups of rats (10 rats in *a*; 9 in *b*). Vertical lines indicate s.e.m. Similar results were obtained for vertical activity. * $P < 0.05$ for comparisons between effects produced by the drugs and the vehicle at each time point.

naloxone-induced hypomotility, however, differed significantly from the saline control level (Fig. 2). This finding seems to suggest the existence in brain of a tonically active enkephalinergic system with a role in modulating some aspects of motor activity.

Standard histological verification of injection sites at the termination of each study revealed that all injections had been made directly into the NA or into regions immediately bordering this structure. Injection sites in the anatomical control group, which had been implanted with cannulae aimed for structures outside the NA, were located in an area 1.5–2.5 mm dorsalateral, and in some cases anterior to, the NA. No hyperactivity was evident in this group after i.c. injections of morphine at any of the time points tested.

Both opiates[11,12] and various catecholaminergic agonists[15–17] have been reported to increase spontaneous motility in rodents after systemic injections. The NA, a terminal region for the mesolimbic dopamine pathways originating from area A10, has been implicated as a principal focus for the excitatory actions of amphetamine[9] and apomorphine[10,18]. These compounds affect activity either by increasing the availability of dopamine at the synapse, or by a direct action on dopamine receptors, as DA receptor blockers antagonise their excitatory actions. Opiates may also increase motility by activating the catecholamine systems[19–21]. Our findings, however, indicate that, at least in the rat forebrain, opiates produce excitatory effects that are dissociated from direct dopaminergic actions. An electrophysiological study, by Cayton and Bradley[22], of striatal neurones also seems to support the notion that dopamine and morphine (enkephalin) may exert identical effects on the same neurone or population of neurones through different receptor systems. These investigators reported that both morphine and dopamine inhibited the induced activation of neurones in the caudate nucleus after iontophoretic applications. The dopamine effect was reversed by a specific dopamine antagonist but not by naloxone while the morphine effect was antagonised by naloxone but not by the dopamine antagonist.

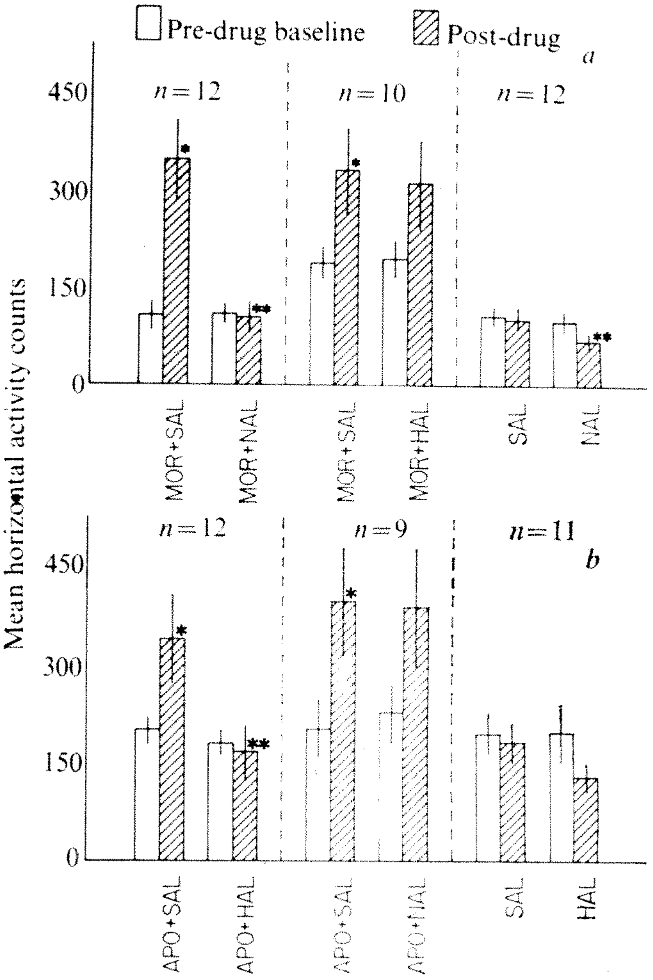

Fig. 2 Effects of naloxone (NAL) 10 mg per kg bodyweight i.p., haloperidol (HAL) 0.25 mg per kg bodyweight i.p. or saline (SAL) 1 ml per kg bodyweight pretreatment on horizontal hypermotility induced by injections of *a*, morphine (MOR), or *b*, apomorphine (APO) in the NA. Right side of figure illustrates the effect of systemically administered NAL (*a*) or HAL (*b*) on spontaneous motility. Similar results were obtained for vertical activity. Some animals were used for more than one drug interaction determination. All drug injections were spaced at least 5 d apart. Baseline activity measures were always determined 1 d before drug injection. Vertical lines indicate s.e.m. * $P < 0.05$ for comparison with baseline activities. ** $P < 0.05$ for comparison of MOR + NAL, and APO + HAL with MOR + SAL and APO + SAL, respectively.

It is possible that parallel neurohumoral systems exist in the forebrain to regulate motility—one encoded by dopamine and the other by enkephalin (the endogenous opiate neuromodulator or neurotransmitter)[8].

Decreased foetal amino acid uptake, brain pyruvate kinase and intrauterine damage in maternal PKU

THE mammalian placenta can concentrate amino acids and release them into the foetal circulation, where they appear at levels higher than on the maternal side[1]. This mechanism provides a larger pool for foetal protein synthesis, but normal placental function can become a handicap in some situations. In the presence of an excess of amino acids the placenta exacerbates the maternal imbalance and produces a prolonged hyperaminoacidaemia in the foetus[2]. This in turn may affect the transplacental transport of other amino acids. Such can be the case in 'material phenylketonuria (PKU)', which often results in offspring with brain damage and mental retardation[3]. Using an animal model of 'maternal PKU' we have studied alterations in tissue levels and placental transport of L-tyrosine (Tyr), L-tryptophane (Trp) and certain foetal brain enzymes. We have found a reduced foetal tissue concentration of Trp and impaired foetal brain uptake of Tyr and Trp in the foetuses of hyperphenylalaninaemic dams, as well as reduced brain pyruvate kinase activity.

Pregnant rats from a homogeneous colony (CFN, Carworth) were fed either a commercial regular ration (C), or the same diet plus 7% L-phenylalanine (Phe) during the last week of gestation (HiPhe). Placental transport was investigated on the day before delivery. One hour before the procedure, HiPhe animals were given an oral bolus of Phe (500 mg kg^{-1}) to ensure consistent hyperphenylalaninaemia throughout the ensuing procedure, comparable with the situation of an untreated case of human PKU. In separate studies we determined that rats limited to the diet with 7% Phe would have 600–1,000 μM Phe in the blood. After anaesthesia with urethane (1.5 g kg^{-1}), rats were injected in the femoral vein with tracer amounts of metabolites tagged with tritium at 40 μCi kg^{-1}, as described[2] and applied[4] before. The identity of the label was checked by thin-layer chromatography and liquid scintillation counting. The brains of some foetuses in each litter were removed immediately and prepared for enzyme assays[5,6]. Free amino acid concentrations were determined in blood and tissues[7,8].

C foetuses had higher concentrations than the corresponding dams for all three aromatic amino acids tested. Foetuses of HiPhe rats had even higher blood Phe than the dams (Table 1). Blood Tyr concentrating were also higher in HiPhe animals. This is a well known feature of this animal model, because high Phe intake inhibits Phe hydroxylase only partially and does not prevent increased formation of Tyr from its precursor, Phe. If the rate of Tyr transport had been similar in both groups of rats, the concentrations on the foetal side in HiPhe foetuses would have exceeded the solubility of Tyr, approximately 3 mM in water at physiological temperatures. Although there were no differences in blood Trp levels in dams fed either one of the two regimes, the foetuses of hyperphenylalanineaemic mothers had very significantly lower blood and brain Trp.

Table 1 Maternal and foetal blood and brain amino acid concentrations, radioactivity after amino acid pulse

Group	Units	Phenylalanine Maternal blood	Phenylalanine Foetal blood	Phenylalanine Foetal brain	Tyrosine Maternal blood	Tyrosine Foetal blood	Tyrosine Foetal brain	Tryptophan Maternal blood	Tryptophan Foetal blood	Tryptophan Foetal brain
Controls	µM	165±41	315±67	355±48	65±11	365±26	798±102	30±6	106±2	126±13

Controls	d p m g^{-1}	—	—	—	66,438±7,159	51,694±4,337	44,581±1,320	38,278±3,390	50,883±4,131	40,735±4,392
HiPhe	d p m g^{-1}	—	—	—	66,027±6,295	53,972±3,964	37,335±2,222*	36,695±2,268	28,523±2,514‡	16,251±1,090†

Values represent the means ± s.e. for 7–18 dams and their litters. Specimens were taken 15 min after injection of the tracers. Foetal brains from whole litters were pooled for the assays. Either 3,5-^{3}H-L-tyrosine, 60 Ci mmol^{-1} or ^{3}H-L-tryptophan, 8 Ci mmol^{-1}, were given at a dose of 40 Ci kg^{-1}.
*$P < 0.02$ compared with controls.
†$P < 0.01$ compared with controls.
‡$P < 0.001$ compared with controls.

Fifteen minutes after pulse of ^{3}H-Tyr, the radioactivity present in maternal and foetal blood was not different in HiPhe and C animals. That reaching the brain, however, was lower in HiPhe foetuses. In contrast, after injection of ^{3}H-Trp, while counts in maternal blood were also similar in the two groups, foetal blood and brain radioactivity was significantly lower in the HiPhe group.

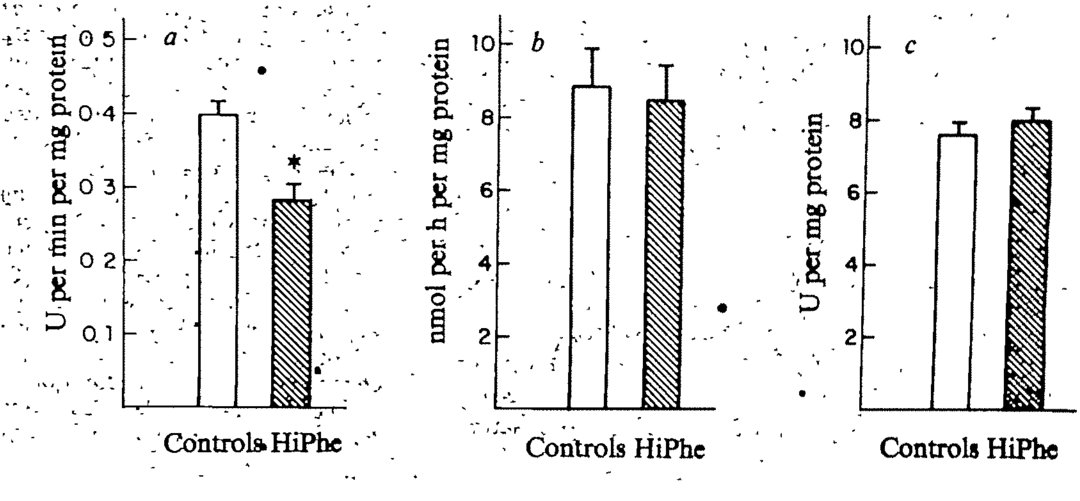

Fig. 1 Foetal rat brain enzymes from C and HiPhe dams. Pyruvate kinase (*a*) and hexokinase (*b*) were determined by the methods of Weber[5] and succinic dehydrogenase (*c*) by the procedure of Adlard and Dobbing[6]. Eight pooled litters were assayed in each group. T, means ±s.e.m. *, $P < 0.01$.

Among the brain enzymes studied, we found that pyruvate kinase was inhibited in HiPhe foetuses, while hexokinase and succinic dehydrogenase were not affected (Fig. 1). These results agree with the findings of several investigators[5,9,10] who showed *in vitro* and *in vivo* inhibition of rat and human brain pyruvate kinase by Phe. Their results yielded a K_i of of 3–5 mM on rat brain pyruvate kinase. Since the mean brain Phe concentration in the HiPhe foetuses was almost 2.5 mM (compare Table 1), seven times higher than in C, and of the same order of magnitude as the reported K_i the occurrence of this effect as a consequence of transplacental overflow of Phe was well justified.

Placental transport of Trp was investigated because the active transport of this amino acid may be inhibited competitively by Phe. It has been postulated that both share an active translocation mechanism[11]. The relevance of Trp to the problem of PKU is also tied to the defect in the metabolism of a Trp derivative, serotonin, considered to occur in that condition[12]. The synthesis of brain serontonin is regulated both by the availability of Trp and its hydroxylation by Trp hydroxylase, the rate-limiting enzymatic step[13,14]. In the animal model used here we have observed that the concentration of Trp in the brain of HiPhe foetuses is sharply decreased and that the transplacental passage of tritiated Trp is also lower in HiPhe dams, indicating that substrate availability is reduced in maternal hyperphenylalaninaemia. Moreover, it has been shown[15] that Phe at 10^{-4} to 10^{-5} M is inhibitory of Trp hydroxylase and Trp uptake by a brain stem synaptosome fraction. Thus, the findings on amino acid concentrations in foetal blood and brain suggest that foetuses exposed to the experimental conditions are at a disadvantage on two accounts for normal brain serotinin synthesis.

In previous studies we observed that hyperphenylalaninaemia was associated with an impaired transport across the small intestine of Phe and Trp, but not of Tyr[16]. A reduction of blood Phe levels was followed by a normalisation of intestinal absorption. In the present investigation we identified another biological membrane where the interaction between Phe and other aromatic amino acids can result in a severe impairment of the transport of Trp, and of Tyr, to a lesser extent. The resulting reduction in foetal blood and brain Trp, as well as the accumulation of Phe in foetal tissues, can provide a better understanding of the biochemical factors likely to be responsible for the *in utero* damage suffered by foetuses of hyperphenylalaninaemic mothers. Increasing foetal availability of Trp by dietary manipulations[17] may have a possible impact of equal magnitude as decreasing maternal blood Phe, a therapeutic approach already suggested in the prevention of otherwise irreversible damage occurring in human 'maternal PKU'[13,18].

Physiological significance of α-adrenoceptor-mediated negative feedback mechanism regulating noradrenaline release during nerve stimulation

NORADRENERGIC nerve endings in the peripheral nervous system are involved in the synthesis, storage, release and uptake of the neurotransmitter. The view that released noradrenaline interacts only with the postsynaptic receptors of the effector cell to elicit the typical response (contraction of a smooth muscle, positive chronotropic and inotropic effects) has been challenged by the proposal that specific receptors might also be present in the outer surface of the membrane of nerve endings[1–5]. These presynaptic receptors are of the α-adrenergic type, mediating a negative feedback mechanism regulating noradrenaline release during nerve stimulation[1–5]. The noradrenaline thus released, on reaching a threshold concentration in the synaptic gap, activates presynaptic α adrenoceptors triggering a negative feedback mechanism that inhibits further release of the transmitter. In support of this view, it has been reported that activation of presynaptic α adrenoceptors leads to a decrease in transmitter release, while blockade of these receptors results in an increase in noradrenaline release during nerve stimulation[5]. We have now demonstrated that the negative feedback mechanism mediated by presynaptic α adrenoceptors has a physiological role in neurotransmission.

In tissues where the effector organ's responses are mediated by α adrenoceptors, block of the presynaptic α receptors enhances noradrenaline release by nerve stimulation, but decreases the responses by blockade of the postsynaptic receptors[2,6]. On the other hand, for tissues in which the responses are mediated by postsynaptic β adrenoceptors, block of presynaptic α receptors should increase noradrenaline release and the responses to sympathetic nerve stimulation. Nevertheless, in the perfused cat heart[7] and in isolated guinea pig atria[8] there are no significant increases in the positive chronotropic responses to nerve stimulation in conditions in which the release of noradrenaline was increased by phentolamine.

An enhancement in transmitter release which is not accompanied by an increase in the response of the effector organ might indicate that the negative feedback mechanism mediated by presynaptic α adrenoceptors does not play a physiological role in noradrenergic neurotransmission. To explore this possibility further, the responses to accelerans nerve stimulation and the increase in transmitter release in isolated guinea pig atria were investigated during and after exposure to the α-receptor blocking agent, phentolamine.

Guinea pig atria with their accelerans nerve, in an isolated organ bath fitted with platinum electrodes for nerve stimulation[9], were immersed in Locke's solution with 1.4 μM atropine. The spontaneous contractions of the preparation were recorded with a force displacement transducer connected to a Grass polygraph. The endogenous noradrenaline stores were labelled with $(\pm)$-7-^{3}H-noradrenaline[9] and the accelerans nerves were stimulated with square pulses of 0.5 ms duration and supramaximal voltage.

The overflow of labelled transmitter elicited by nerve stimulation was calculated as fractional release per shock :

Table 1 Effects of phentolamine on ^{3}H-noradrenaline release elicited by nerve stimulation in guinea pig atria

		Fractional release per shock ($\times 10^{-4}$)			Ratio	
Experimental group	*n*	S_1	S_2	S_3	S_2/S_1	S_3/S_1
Control	6	1.11 ± 0.18	1.12 ± 0 22	0.89 ± 0 17	1 03 ± 0 11	0 80 ± 0.09
Phentolamine 0.31 μM	6	1.38 ± 0 28	4.42 ± 0.55†	2.33 ± 0 30*	3 65 ± 0.62*	1.92 ± 0 30*
Phentolamine 3.1 μM	6	1.23 ± 0.14	6.67 ± 1 65†	4.39 ± 0 76†	6.09 ± 0.73‡	3 51 ± 0 30‡

Fractional release per shock is expressed as total nCi released per shock divided by the total nCi remaining in the tissue at the onset of nerve stimulation (4 Hz, during 60 s, with supramaximal voltage). Phentolamine (0.31 or 3.1 μM) was added to the medium 30 min before S_2 and washed out 5 min after S_2. The interval between each period of nerve stimulation was 50 min. Mean values ± s.e.m. are shown *n*, Number of experiments.

* $P < 0\ 05$ compared with the control.

† $P < 0.025$ compared with control.

‡ $P < 0\ 005$ compared with control

total nCi released per shock divided by the total nCi remaining in the tissue at the onset of stimulation[10] Dose–response curves to exogenous noradrenaline were determined cumulatively[11].

During exposure to 0 31 μM phentolamine there was a nearly fourfold increase in ^{3}H-transmitter release elicited by nerve stimulation (Table 1). The enhancement in transmitter release was still observed after the α-blocking agent was removed from the perfusion medium (Table 1)

We studied, separately, the positive chronotropic effects of accelerans nerve stimulation at low frequencies After four control periods of nerve stimulation, 0 31 μM phentolamine was added to the medium and a significant increase in the responses to nerve stimulation was obtained (Fig. 1) As observed for the effects of phentolamine on ^{3}H-transmitter release, the potentiation of the chronotropic responses elicited by nerve stimulation persisted after the α-receptor blocking agent was removed from the perfusing medium (Fig 1)

The effects of phentolamine on transmitter release were concentration-dependent (Table 1) When the positive chronotropic responses to nerve stimulation were determined in the presence of 3.1 μM phentolamine, however, the increase in responses to nerve stimulation was not statistically significant in the controls the rate was increased by 31 ± 7 beats per min, while in the presence of 3 1 μM phentolamine the increase was 47 ± 8 beats per min ($n = 10$, $P > 0.05$) The absence of a significant potentiation in the responses to nerve stimulation in the presence of 3 1 μM phentolamine seems to be related to the ability of the α-receptor blocking agent to elicit a negative chronotropic effect and to antagonise responses of the atrial pacemaker to noradrenaline. Exposure to phentolamine produced a negative chronotropic effect which was concentration-dependent The maximum decrease in atrial rate was obtained with 31 μM phentolamine a reduction by 51 ± 4 beats per min (mean ± s e m of 13 experiments) During exposure to 3 1 μM phentolamine the rate decreased by 16 ± 3 beats per min ($n = 13$) The negative chronotropic effect of phentolamine seems to be veratramine-like[12] since there was a significant correlation between the initial rate and the magnitude of the negative chronotropic effect of phentolamine: the higher the atrial rate, the more pronounced the negative chronotropic effect ($r = 0\ 708$, $P < 0\ 01$, $n = 25$).

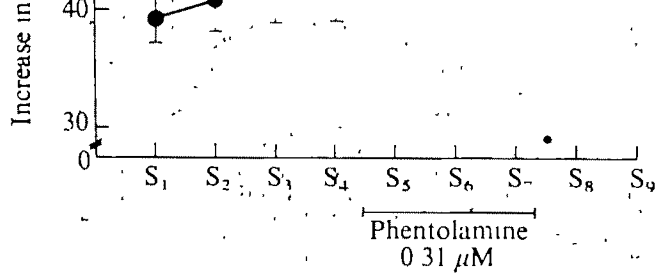

Fig. 1 Potentiation by phentolamine of the positive chronotropic effects of accelerans nerve stimulation in isolated guinea pig atria Increase in atrial rate induced by nerve stimulations S_1–S_9 at 0.5 Hz, for 10 s, supramaximal voltage The interval between each nerve stimulation was 20 min Phentolamine (0 31 μM) was added to the medium 10 min before S_4 and kept until 10 min after S_7 In the absence of phentolamine the responses to nerve stimulation were sustained from S_1 to S_9 Mean values ± s.e m of 11 experiments are shown * $P < 0.05$ compared with S_1.

Exposure to 31 μM phentolamine produced a marked negative chronotropic effect and a shift to the right in the dose–response curve to exogenous noradrenaline (Table 2).

Table 2 Antagonism by phentolamine of the positive chronotropic responses to noradrenaline in isolated guinea pig atria

			Responses to (−)-noradrenaline	
Experimental group	*n*	Initial rate* (beats per min)	pD_2†	Maximum increase‡
Controls	6	209 ± 9	6.82 ± 0.13	119 ± 10
Phentolamine 31 μM	8	136 ± 8‖	5.54 ± 0.27§	135 ± 7

* Rate before the beginning of the concentration effect curve to exogenous noradrenaline

† Mean negative log molar ED_{50}.

‡ Maximum increase in atrial rate (in beats min^{-1}) in response to (−)-noradrenaline

Mean values ± s.e m are shown *n*, number of experiments

§ $P < 0\ 05$ compared with control.

‖ $P < 0\ 001$ compared with control.

Phentolamine (3.1 μM) also reduced the positive chronotropic responses to noradrenaline. The positive chronotropic effects of 6 and 18 nM noradrenaline were 15 ± 2 and 22 ± 4 beats per min, respectively (mean ± s.e m. of six observations). In the presence of 3.1 μM phentolamine these values were reduced to 4 ± 1 and 10 ± 3 beats per min (mean ± s.e.m. of seven observations, $P < 0\ 025$ and $P < 0.001$, respectively).

The antagonism by phentolamine of responses of the atrial pacemaker to noradrenaline probably explains why the responses to accelerans nerve stimulation were not increased, during exposure to 3.1 μM α-receptor blocking agent, in spite of the considerable increase in transmitter release (Table 1).

With the concentration of phentolamine lacking negative chronotropic effects (0.31 μM), a significant increase in responses to nerve stimulation was obtained (Fig. 1) when the release of noradrenaline was enhanced (Table 1). This increase in response supports the view that the negative feedback mechanism mediated by presynaptic α-adrenoceptors plays a major physiological role in the regulation of noradrenergic neurotransmission.

Rapid test to detect agents that damage human DNA

PERHAPS the most successful screening test to detect potential mutagens and/or carcinogens is that of Ames *et al*[1], using *Salmonella*. Attempts to use mammalian cells have generally involved measuring some cellular response to DNA damage, for example, induction of DNA repair[2]; if the response implies that an agent has damaged the DNA, the agent is considered to be a potential mutagen and/or carcinogen. An early response to DNA damage in human cells is inhibition of DNA synthesis. But certain non-DNA-damaging agents also inhibit DNA synthesis. I show here that DNA-damaging and non-DNA-damaging agents can be distinguished by the changes in the rates of DNA synthesis after treatment. with a DNA-damaging agent, the rate of DNA synthesis continues to decrease, but with a non-DNA-damaging agent the rate of DNA synthesis increases after treatment.

The test measures thymidine uptake into the DNA of human (HeLa) cells at various times after treatment with a presumptive mutagen or carcinogen The results with several known mutagenic agents (Fig. 1*a*–*d*) show that in every case the amount of thymidine incorporated into the DNA decreased during the first 1–2 h after the end of treatment (after removal of the medium containing the chemical or removal of the cells from the radiation field). Ethyl methanesulphonate (EMS) gave results similar to those with methyl methanesulphonate (MMS), except that 10 mM EMS was required to obtain positive results (data not shown). Benzpyrene requires metabolic activation, and when benzpyrene was incubated with HeLa cells and a microsomal preparation from rat liver, the S-9 mixture[1], it was active, whereas alone it was not. In some experiments ^{3}H-leucine was used to measure protein synthesis during the same time that ^{14}C-thymidine was used to measure DNA synthesis. This is illustrated for 4-nitroquinoline-1-oxide (4NQO) only, but in all cases tested the effect of the agent on protein synthesis was less than the effect on DNA synthesis.

Agents that inhibit DNA synthesis but do not damage DNA—cycloheximide, hydroxyurea, dimethyl sulphoxide, and $NiCl_2$—were also tested (Fig. 2) In contrast to the results with DNA-damaging agents, the rate of thymidine incorporation into DNA increased rapidly immediately after the removal of these agents from the medium (although complete recovery sometimes took a few hours). Phorbol myristate acetate, a so-called promoter of carcinogenesis, was also found in this class (data not shown).

We explain this difference between the two classes of agents that inhibit DNA synthesis as follows When an agent that inhibits by metabolic means is removed from the medium, the metabolic block is removed, recovery begins immediately, and the rate of DNA synthesis increases. When a DNA-damaging agent is removed from the medium,

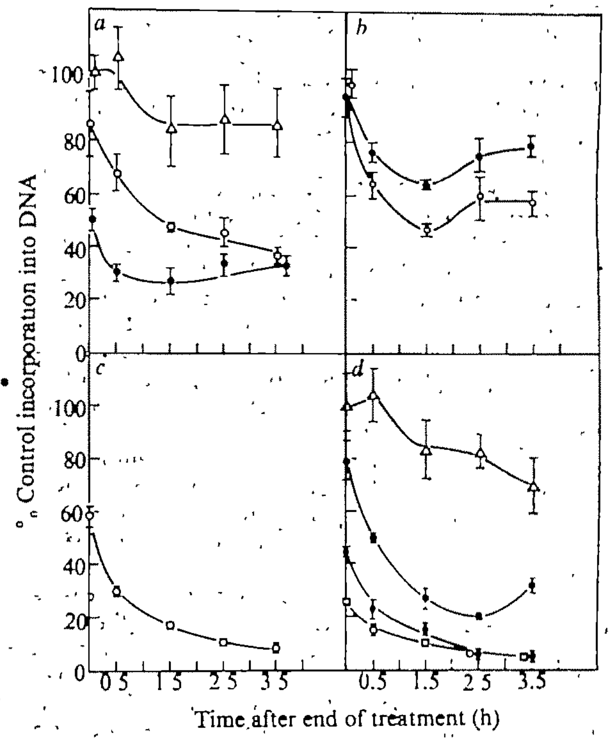

Fig. 1 Rate of DNA synthesis, measured as percentage of control incorporation of thymidine into DNA, in HeLa cells at various times after treatment with *a*, benzpyrene; *b*, MMS; *c*, ultraviolet light (10 J $\mathrm{m^{-2}}$), *d*, 4NQO *a*, △, 7 μM; ○, 7 μm + S-9; ● 20 μm + S-9. *b*, ●, 0.5 mM, ○, 1 mM. *d*, △, 0.2 μM (protein synthesis); ●, 0.2 μM; ◆, 1 μM; ○, 2 μM HeLa cells were grown in Eagle's minimal essential medium (MEM) with 15% calf serum 4NQO was dissolved in alcohol at 0.2 mM Benzpyrene was dissolved in alcohol at 1 mM and diluted into McCoy's 5a medium containing 2.5% calf serum and a 1/20 dilution of S-9 mix, a microsomal preparation from rat liver prepared from animals previously injected with Aroclor, a polychlorinated biphenyl[1] Some cultures were treated with benzpyrene in McCoy's medium without S-9 mix The S-9 mix was simultaneously tested and found to have no effect on DNA or protein synthesis at the dilutions used Incubation times were 30 min for MMS and 4NQO and 1 h for benzpyrene Ultraviolet light irradiations were performed on cells under saline at 1.3 J $\mathrm{m^{-2}\,s^{-1}}$. Immediately after incubation with the chemical or after exposure to ultraviolet light, the medium was removed from all cultures (including controls, which were treated identically except for treatment with the agent to be tested), and Eagle's MEM was placed back on all but two controls and two cultures treated with the agent These were immediately incubated for 10 min with MEM containing either ^{14}C-thymidine (0.3 μCi $\mathrm{ml^{-1}}$, 50 mCi $\mathrm{mmol^{-1}}$) and ^{3}H-leucine (10 μCi $\mathrm{ml^{-1}}$; 84 Ci $\mathrm{mmol^{-1}}$) or ^{3}H-thymidine (10 μCi $\mathrm{ml^{-1}}$; 50 Ci $\mathrm{mmol^{-1}}$) alone. (When ^{3}H-thymidine was used, the cells had been incubated for 24 h or more with 0.02 μCi $\mathrm{ml^{-1}}$ ^{14}C-thymidine before treatment with the agent.) At each of the times indicated, two more controls and two more treated cultures were incubated in radioactive medium for 10 min. The cells were washed after each incubation, scraped into SSC (0.15 M sodium chloride, 0.015 M sodium citrate), and filtered through GF/C (Whatman) glass filters moistened with cold 4% perchloric acid The filters were washed with cold 4% perchloric acid, 70% alcohol, and 100% alcohol, dried, and added to vials containing scintillation fluid, their ^{14}C and ^{3}H content was measured by liquid scintillation spectrometry. Error bars indicate the range of values obtained in a single experiment.

Organic Spectroscopy

WILLIAM KEMP

An introduction to the application of spectroscopic techniques to organic chemistry, suitable for undergraduates meeting these techniques for the first time. The very latest advances in this field are discussed in special supplements at the end of each chapter, thus making the text valuable to the more advanced students without interrupting the exposition of basic principles.

hardcover £7.95 paperback £2.95

Facts & Theories of Aromaticity

DAVID LEWIS AND DAVID PETERS

Published fifty years after J. W. Armit and Sir Robert Robinson proposed their aromatic sextet rule, this book applies the most rigorous available quantum mechanical methods to aromatic systems in order to understand what distinguishes them from non-aromatic systems. The treatment is critical and concise and will be of interest to both theoretical chemists and experimentalists.

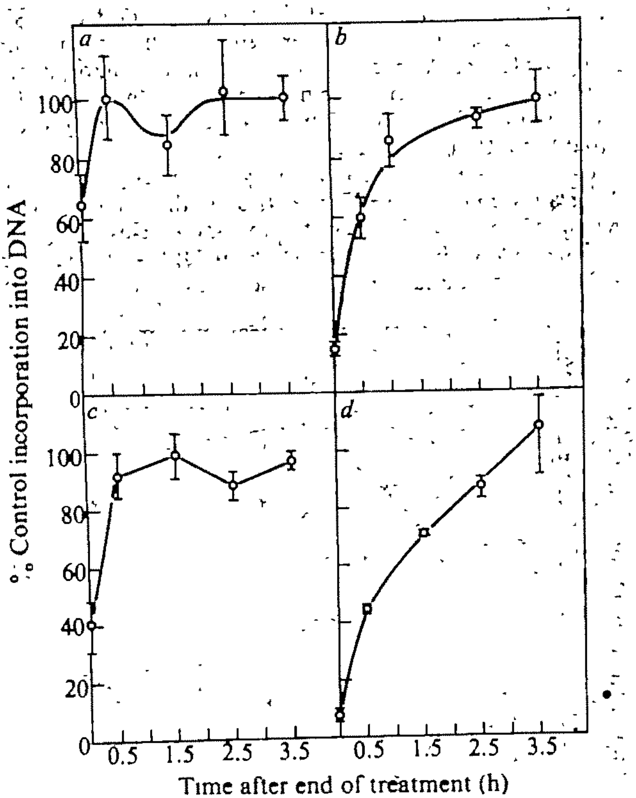

Fig. 2 Rate of DNA synthesis in HeLa cells at various times after treatment with agents that inhibit DNA synthesis by metabolic mechanisms. Conditions were the same as for Fig. 1. *a*, $NiCl_2$ (5 mM); *b*, DMSO (1.3 M); *c*, cycloheximide (23 μM); *d*, hydroxyurea (1 mM).

however, the damage remains, and the rate of DNA synthesis decreases with time. This occurs for one or both of two reasons. First, certain agents, such as ultraviolet light, induce lesions that block the progression of growing points in replicating DNA[4,5] so that progressively fewer growing points remain in operation, until repair occurs. Second, other agents, such as X rays[6–8] and MMS[9], block initiation of replicons, so that as more and more replicons terminate after damage is incurred, DNA synthesis progressively decreases[10].

My results suggest that measurements of DNA synthesis within the first 1–2 h after treatment with an agent can determine its potential as a DNA-damaging agent and therefore as a mutagenic and potentially carcinogenic agent. The simplest procedure is to label HeLa cells for one generation or more (≥24 h) with ^{14}C-thymidine before treatment and to pulse with ^{3}H-thymidine for 10 min at various times after treatment, comparing the resulting $^{3}H/^{14}C$ ratios with those measured at the same times in controls. Although, in many of the experiments reported here prelabel was omitted, so that synthesis of both protein (with ^{3}H-leucine) and DNA (with ^{14}C-thymidine) could be measured after treatment, it is not necessary to measure the former to detect DNA-damaging agents. Furthermore, the use of ^{14}C-thymidine to label parental DNA before treatment with the suspected agent makes possible greater flexibility; for example, care need not be taken to put exactly the same number of cells in each plate, because the resulting $^{3}H/^{14}C$ ratios are independent of cell number.

The experiment using S-9 demonstrates that the method can detect agents requiring metabolic activation. Cyclophosphamide, which also requires activation, required a 2.5× greater concentration of S-9 to achieve activation (data not shown) than did benzpyrene. Thus, each agent needs to be tested for the optimal conditions for activation, as has been reported for other detection systems[3].

The results with $NiCl_2$ require comment. Nickel in the metallic form has been shown to be carcinogenic in rodents[11]. Unpublished work in my laboratory, however, has shown that $NiCl_2$ inhibits DNA synthesis by slowing (not blocking) the rate of chain elongation, in a manner similar to cycloheximide[12] and hydroxyurea[13], and therefore is presumably not a DNA-damaging agent.

The advantages of my method for detecting DNA-damaging agents are: (1) HeLa cells are of human origin and are probably representative of the reaction of other human cells—presumably other rapidly growing human cells could also be used; (2) HeLa cells are easy to grow and do not exhibit contact inhibition, so that enough cells can easily be obtained in a 35-mm Petri dish or other small test vessel for a single determination; (3) the test requires only about 2 h from the first addition of the agent to the end of the last incubation, and (4) the assay is extremely simple—no extraction procedures are necessary because the whole cells are precipitated on to filters, which are dried and counted by conventional procedures. The disadvantages are similar to those of other systems based on DNA damage, for example the system will not detect mutagens, such as asbestos, that act through unknown mechanisms. False positives do not seem to be a factor. Possibly some agent could act so that metabolism in general, and consequently DNA synthesis, would continue to decrease with time after the agent has been removed from the cell. Experiments with KCN, however, suggest that this is unlikely. KCN at 15 and 30 mM decreased the DNA synthesis rates to about 25 and 15% of the controls, respectively; nevertheless, after KCN was removed, recovery of DNA synthesis began immediately for the lower concentration and within 1.5 h for the higher. Thus, recovery of DNA synthesis occurs from even a powerful general poison, as long as no DNA damage is incurred. It seems possible, therefore, that this simple test might be useful as a screening procedure to detect agents that damage human DNA.

I thank Ms Ricci Howard for technical assistance, Drs S. Wolff and J. E. Cleaver for chemicals, and Ms Judy Bodycote for preparation of the liver microsomes. This work was performed under the auspices of ERDA.

Functional identity of a mouse ascites and a rabbit reticulocyte initiation factor required for natural mRNA translation

INITIATION of eukaryotic protein synthesis involves the assembly of a functional initiation complex from components including ribosomal subunits, initiator tRNA (Met-$tRNA_F$), initiation factors, messenger RNA, ATP and GTP[1–3]. Much research in this area has centred on the possible control of eukaryotic translation at the level of polypeptide initiation, as this step seems to be rate-limiting in the overall synthetic reaction[4,5]. Some studies have suggested the existence of tissue-specific initiation factors[6], others have described initiation factors which apparently discriminate between eukaryotic mRNAs[7]. Work in this laboratory led to the purification of an initiation factor of molecular weight 53,000 from the supernatant fraction of Krebs II ascites cells[8]. This factor ($\mathrm{IF_{EMC}}$) was shown to be required for the translation of encephalomyocarditis virus RNA (EMC RNA) but not for globin mRNA translation in a fractionated ascites cell-free system[8]. Other studies on the translation of mRNAs injected into living *Xenopus laevis* oocytes[10], and on the translation of various mRNAs in several crude eukaryotic protein-synthesising systems[11] have suggested, however, that eukaryotic translation proceeds without controls exerted by specific initiation factors. We have adopted a comparative approach to this problem, examining the translation of various eukaryotic mRNAs in a fractionated cell-free system from Krebs II ascites cells, and testing the specificity of two mammalian factors reported to be required for the initiation of natural mRNA translation.

The specificity of the $\mathrm{IF_{EMC}}$ factor was investigated further (Table 1). Our results confirm work demonstrating requirement for $\mathrm{IF_{EMC}}$ in EMC RNA translation[8]. Translation of mengo virus RNA and foot-and-mouth disease virus RNA was also dependent on the addition of $\mathrm{IF_{EMC}}$. Some mRNAs, however, showed no significant dependence on $\mathrm{IF_{EMC}}$ for translation (for example, tobacco mosaic virus RNA), whereas others showed a partial stimulation of translation by $\mathrm{IF_{EMC}}$ (for example, Semliki forest virus 26S RNA). Our studies have shown a wide spectrum of dependencies on $\mathrm{IF_{EMC}}$ for the translation of several mRNAs, and have demonstrated differences in the efficiency of their translation in the fractionated cell-free system. For example, RNAs from two closely related picornaviruses[14], namely EMC and polio, show differences both in their extent of translation and in their requirement for $\mathrm{IF_{EMC}}$. It is therefore possible that other factors, necessary for translation of mRNAs such as polio RNA, may be either absent or present in suboptimal concentrations in the fractionated cell-free system.

An apparent analogue of Krebs ascites $\mathrm{IF_{EMC}}$ termed IF-E4 (ref. 2) or IF-M4 (ref. 13), has been recognised in rabbit reticulocytes, and is similar to $\mathrm{IF_{EMC}}$ in molecular weight and chromatographic behaviour. We therefore compared the requirement for $\mathrm{IF_{EMC}}$ and IF-E4 in EMC RNA translation in the $\mathrm{IF_{EMC}}$-deficient ascites cell-free system (Fig. 1). $\mathrm{IF_{EMC}}$ and IF-E4 were equally efficient in stimulating EMC RNA translation at saturating factor concentration. The greater specific activity shown by IF-E4 presumably reflects the higher purity of this factor compared with $\mathrm{IF_{EMC}}$.

We then examined separately the specificity of IF-E4 in the translation of several mRNAs in the ascites cell-free system (Table 2). The results correspond closely to those obtained with $\mathrm{IF_{EMC}}$ (Table 1). EMC RNA, mengo virus RNA and foot-and-mouth disease virus RNA require the

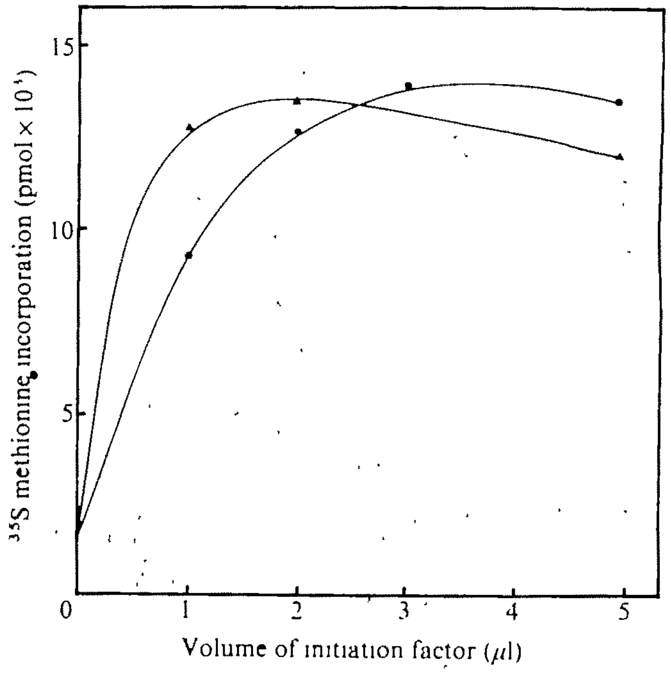

Fig. 1 Dependence of EMC RNA translation in the ascites fractionated cell-free system on $\mathrm{IF_{EMC}}$ (from Krebs ascites cells) (●) and IF-E4 (from rabbit reticulocytes) (▲). Protein synthesis assays were performed as described in Table 1, containing 0.02 A_{260} units EMC RNA and increasing volumes of $\mathrm{IF_{EMC}}$ (protein concentration 1 mg ml^{-1}) or IF-E4 (protein concentration approximately 0.3 mg ml^{-1}). Incorporation in the presence of EMC RNA was corrected for a value of 0.0094 pmol ^{35}S-methionine obtained in the absence of added EMC RNA. No alteration in this background value was observed on addition of either initiation factor. 1 pmol $\approx 26 \cdot 10^4$ c.p.m.

Table 1 Effect of the addition of Krebs ascites cell $\mathrm{IF_{EMC}}$ on the translation of various mRNAs in the fractionated ascites cell-free system

mRNA	^{35}S-methionine incorporation (pmol × 10^3) Control	 Control + $\mathrm{IF_{EMC}}$	Stimulation by $\mathrm{IF_{EMC}}$ (% control value)
Encephalomyocarditis virus	7	55	686
Mengo virus	5	88	1,660
Foot-and-mouth disease virus	18	62	233
Polio virus	11	10	0
Semliki forest virus (42S RNA)	15	12	0
Semliki forest virus (26S RNA)	12	18	50
Vaccinia virus *in vitro* mRNA	26	27	4

Brome mosaic virus	11	13	18
Satellite tobacco necrosis virus	34	48	37
Tobacco rattle virus	45	56	24
Haemoglobin mRNA	10	14	40
Oviduct polysomal RNA	12	10	0

The components of the fractionated ascites cell-free system were prepared as previously described[9]. Protein synthesis assays were performed in 25-µl reaction mixtures containing 0.45 A_{260} units ascites ribosomes, 5 µg elongation factor 1, 0.02 A_{260} units ^{35}S-methionine–tRNA (0.8 pmol ^{35}S-methionine), 1–6 µg mRNA, 1–2 µg $\mathrm{IF_{EMC}}$, 20 mM Tris-HCl (pH 7.5), 3.5 mM $MgCl_2$, 100 mM KCl, 6 mM 2-mercaptoethanol, 1 mM ATP, 0.1 mM GTP, 8 mM creatine phosphate and 100 µg creatine phosphokinase. The ionic conditions were optimal for several mRNAs tested, that is, EMC RNA, Semliki forest virus 26S RNA and tobacco mosaic virus RNA. $\mathrm{IF_{EMC}}$ (purified to the Sephadex G-100 stage[8]) and each mRNA was added in saturating concentration. Incubation was at 37 °C for 30 min. Hot trichloroacetic acid-precipitable radioactivity was measured as previously described[9]. Incorporations in the presence of mRNA were corrected for background incorporation of 0.010 pmol ^{35}S-methionine in the absence of added mRNA. 1 pmol ^{35}S-methionine is approximately equivalent to 25 10^4 c.p.m.

Table 2 Effect of the addition of rabbit reticulocyte IF-E4 on the translation of various mRNAs in the fractionated ascites cell-free system

mRNA	^{35}S-methionine incorporation (pmol × 10^{3}) Control	Control × IF-E4	Stimulation by IF-E4 (% control value)
Encephalomyocarditis virus	28	142	410
Mengo virus	28	159	470
Foot-and-mouth disease virus	51	222	335
Polio virus	48	52	8
Vaccinia virus *in vitro* mRNA	46	48	4
Tobacco mosaic virus	178	179	0
Brome mosaic virus	62	80	3
Tobacco rattle virus	168	177	5
Satellite tobacco necrosis virus	111	126	14
Haemoglobin mRNA	14	22	57
Oviduct polysomal RNA	39	52	33

Protein synthesis directed by each mRNA was assayed at saturating mRNA concentration as described in Table 1 and the effect of the addition of a saturating amount of IF-E4 was tested. Incorporations in the presence of mRNA were corrected for background incorporation of 0.015 pmol ^{35}S-methionine in the absence of added mRNA. 1 pmol ^{35}S-methionine is ≈ 19 × 10^{4} c.p.m.

addition of IF-E4 for translation, whereas the remainder of the mRNAs tested show either no significant dependence (for example, tobacco mosaic virus RNA) or a partial dependence (for example, oviduct polysomal RNA) on IF-E4 for translation. The optimal concentration of monovalent and divalent cations for EMC RNA translation in the presence of either IF$_{\mathrm{EMC}}$ or IF-E4 was tested and found to be the same for either factor, that is, optimal translation was obtained at 100 mM KCl and 3.5 mM MgCl$_2$. In common with IF$_{\mathrm{EMC}}$, IF-E4 is required for the synthesis of EMC-specific initiation peptides formed in the presence of sparsomycin[14], an inhibitor of polypeptide elongation, suggesting that both factors act at the level of initiation of protein synthesis.

Staehelin's group has shown that IF-E4 is required for the translation of both globin mRNA and EMC RNA in a completely fractionated protein-synthesising system[2]. Moreover, a twofold higher concentration of IF-E4 was required for optimal EMC RNA translation than for globin mRNA translation. Because EMC RNA is larger than globin mRNA, in molar terms this represents a greater IF-E4 requirement for EMC RNA translation, suggesting that the amount of IF-E4 required for optimal translation varies according to the mRNA tested. Our results are consistent with these findings. The high requirement for IF$_{\mathrm{EMC}}$ in EMC RNA translation is expressed by the need to add exogenous factor to the fractionated ascites cell-free system for translation to proceed. A low level of IF$_{\mathrm{EMC}}$ contamination of the ascites cell-free system could explain the absence of dependence or partial dependence on IF$_{\mathrm{EMC}}$ for the translation of several mRNAs (Table 1). In support of this idea, we have detected IF$_{\mathrm{EMC}}$ activity in a 350 mM KCl wash of the ribosomes used in the standard protein synthesis assay. We were unable to prepare ribosomes devoid of IF$_{\mathrm{EMC}}$ which retained good activity in natural mRNA translation in the fractionated cell-free system.

Hellerman and Shafritz have suggested that certain initiation factors bind to mRNA[15]. Thus both the Met-tRNA$_{\mathrm{f}}$ binding factor and messenger ribonucleoproteins (mRNPs) from rabbit reticulocytes bound to globin mRNA and poly(A). A polypeptide of molecular weight 52,000 was found both in the initiation factor and the mRNP preparation. In spite of the close similarity in molecular weight of this polypeptide to IF$_{\mathrm{EMC}}$, we could not demonstrate co-electrophoresis in sodium dodecylsulphate (SDS) gels of IF$_{\mathrm{EMC}}$ with any of the proteins of ascites mRNPs. This suggests that IF$_{\mathrm{EMC}}$ does not form a stable association with mRNA.

We conclude that IF$_{\mathrm{EMC}}$ and IF-E4 are functionally identical and have analogous roles in the initiation of protein synthesis in rabbit reticulocytes and mouse ascites cells. This factor is therefore not specific to cell, tissue or species but may be required in variable amounts for the translation of all mRNAs. It is interesting that variable amounts of the prokaryotic initiation factor IF3 are needed for the translation of different bacterial mRNAs[16]. IF3 may stabilise the direct base-pairing between the 5′ terminus of mRNA and the 3′ end of 16S ribosomal RNA shown to be important in the initiation of prokaryotic protein synthesis[17]. We speculate that IF$_{\mathrm{EMC}}$ and IF-E4 effect a similar stabilisation in eukaryotic mRNA–ribosome interaction[18].

We thank our colleagues for mRNAs, Dr T. Staehelin for rabbit reticulocyte IF-E4 and Professor K. A. Marcker for help and discussion. G.E.B. received an EMBO fellowship and J.C.L. received financial support from INSERM and NATO.

A search for *in vivo* factors in regulation of microtubule assembly

MICROTUBULES are abundant in eukaryotic cells where they assume various functions[1], some of which seem to be at a purely structural level, such as maintenance of cell shape and axonal elongation, whereas others are involved in more dynamic processes, such as mitosis, meiosis, secretion and axonal transport. At least two distinct protein factors of

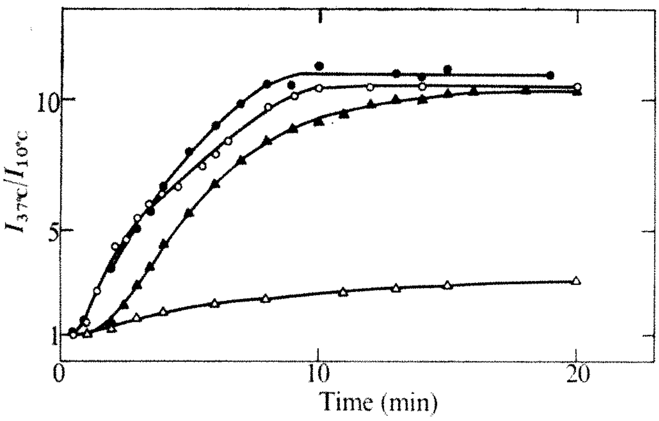

Fig. 1 For preparation of microtubules, rat brains were homogenised in 2 volumes of MES buffer and microtubules polymerised from the 105,000*g* supernatant using the method of Shelanski *et al*[11]. The pellets obtained after centrifugation for 30 min at 50,000 r.p.m. and 25 °C, in a Spinco 50 rotor, were washed, and after resuspension, depolymerised for 30 min at 0 °C. The supernatant obtained after 30 min of centrifugation at 40,000 r.p.m. and 0 °C, in a Beckman 50 rotor, was used to analyse the kinetics of microtubule selfassembly by light scattering, electron microscopy and analytical ultracentrifugation. The rate of polymerisation of brain homogenates was followed by monitoring the time dependence of their scattering at 37 °C at an angle of 90° in a Fica light scattering photometer. The ratio of scattering at 37 °C to that at 10 °C (I_{37}/I_{10}), reflecting the polymerisation process was measured in the absence (open symbols) and presence of glycerol (solid symbols) on brain homogenates from 5-d-old (△) and 30-d-old rats (○). Similar scattering patterns were observed for solutions obtained after a one-cycle polymerisation purification. At 10 °C no change in scattering of solutions was detected during the experiments.

different molecular weight have been suggested[2-5] to regulate microtubule assembly. The uniqueness of their role is not unequivocally established because microtubules have also been obtained in the absence of these protein factors, at high magnesium ion concentrations[6], in the presence of polycations[7] or glycerol[11]. To correlate better the results obtained *in vitro* with the mechanism operating *in vivo*, we have studied the assembly of microtubules in extracts prepared from developing rat brain, differentiating mouse neuroblastoma cells and in chicken sensory ganglia, which may facilitate detection of a factor which induces self-assembly *in vivo*. We conclude that the high molecular weight protein is seemingly not required for the *in vivo* assembly of microtubules.

The rate and extent of polymerisation of microtubules, as measured by light scattering, in soluble extracts prepared from brains of 5-d-old rats was much lower than in extracts from 30-d-old rat brains (Fig. 1). This confirms observations made by Fellous *et al.*[9-10]. Glycerol promotes tubulin assembly[11], and in the presence of glycerol the polymerisation rate of the extract of 5-d-old brain was considerably increased, reaching a level comparable with that of the 30-d-old extract. Depolymerised microtubules prepared from 5-d-old rat brains did not show the ring component in the analytical centrifuge (36S) that was present in extracts from adult animals (Fig. 2). Electron micrographs of these extracts confirm that rings were present only in the 30-d extract. Our measurements of the 'ring' peak indicate a sedimentation coefficient of 30–33S. Thus, as our preparation procedures were similar to those of Shelanski *et al.*[11], we conclude that we are dealing with the native tubulin ring sedimenting at 36S, rather than the 42S ring component whose formation was induced by a high magnesium level (see ref. 8, page 4565).

These data raise two main questions: are the microtubules formed in the presence of glycerol similar to those polymerised in its absence, and is there a correlation between the higher rate of polymerisation of microtubules in extracts from mature brains and the presence of 'rings' and other protein species absent from extracts of younger animals? We have observed that microtubules polymerised in the presence or absence of glycerol have the same gross morphology and optical diffraction patterns of their micrograps display identical periodicities. Thus with respect to periodic features the two species are indistinguishable. It should be noted, however, that microtubules polymerised in the presence of glycerol have been reported to contain different amounts of accessory proteins. The presence of glycerol also leads to the formation of rings of apparently different shape or subunit composition, as reflected by their sedimentation coefficients[12].

Rings cannot be formed from purified 6S tubulin, but they can be assembled in the presence of a high molecular weight protein which has yet to be fully characterised[3-5] or in the presence of high magnesium concentration[8], albeit with apparent change in their structure in the latter case. To test for the presence of this protein factor, extracts were analysed by electrophoresis on SDS–polyacrylamide gels (Fig. 3). There was no clear correlation between the relative content of high molecular weight protein in the extract and the speed of polymerisation, and the relative amount of this protein in microtubules did not correlate with the animal's age. These results suggest that the high molecular weight protein, although able to induce *in vitro* microtubule assembly, is not required for *in vivo* polymerisation. In line with this conclusion is our inability to detect high molecular weight protein by autoradiography of sodium dodecyl sulphate (SDS)–polyacrylamide gels of microtubules from differentiating neuroblastoma cells[13] or sensory ganglia exposed to nerve growth factor (unpublished observations by H. Schmitt and S. Mizel), labelled with ^{3}H-leucine or ^{35}S-methionine.

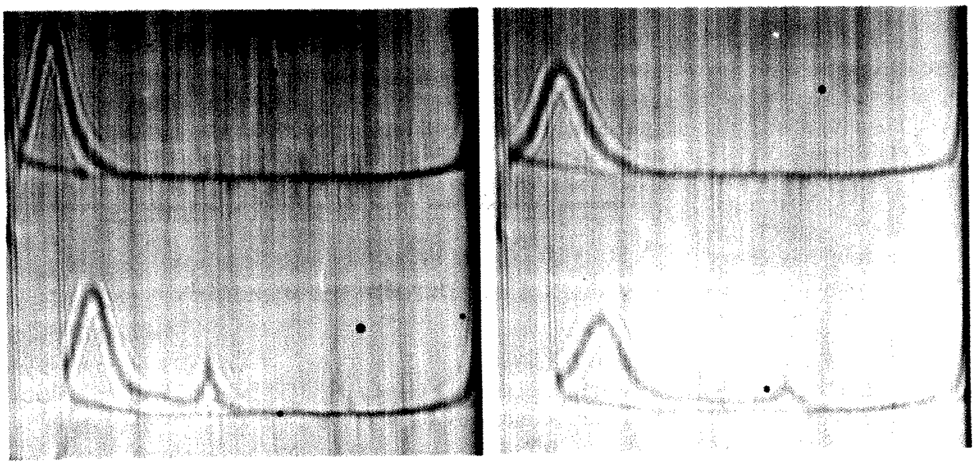

Fig. 2 Schlieren pattern of tubulin sedimenting in the ultracentrifuge at 44,000 r.p.m. and 7 °C. The upper cell contained tubulin from 5-d-old rat brain, and the lower cell, tubulin from 30-d-old rat brain. The first pattern was obtained after 16 min and the second pattern after 32 min of sedimentation. The upper pattern has only a single 6S peak and the lower cell has a 6S and a 36S peak. Electron microscopy confirms that the 36S component consists of rings.

On the other hand, a protein with a molecular weight, on SDS–polyacrylamide gels of 82,000 was reproducibly found in microtubules prepared from brains of rats older than 10 d and not from younger animals (Fig. 3). The molecular weight of this protein is similar to that of τ factor, first described by Weingarten *et al.*[5,14,15]. This observation supports the report by Fellous *et al.*[10] that partially purified τ factor enhances the rate of polymerisation of microtubules from extracts of young rat brains and raises the possibility that it interacts with tubulin and facilitates polymerisation. A more definitive indication of the role of this protein will be obtained if it can be shown to be associated with microtubules polymerising *in vivo.*

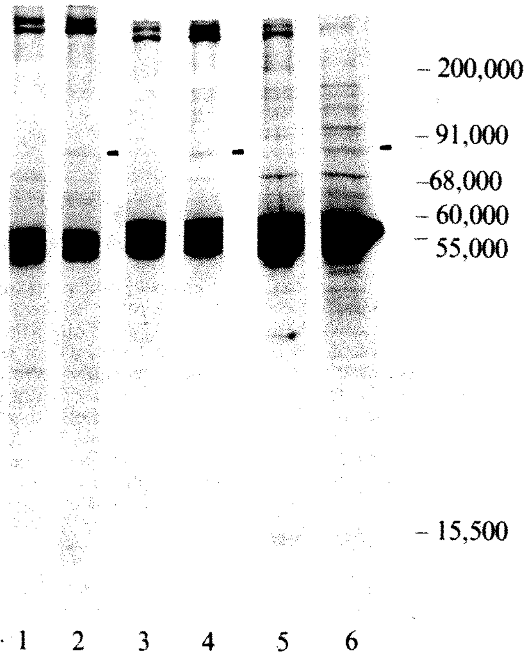

Fig. 3 SDS–polyacrylamide gel analysis of polymerised microtubules from 5- and 30-d-old rat brains. Microtubules were purified by one-cycle of self-assembly as described in Fig. 1. Pellets were resuspended and analysed on 10–20% polyacrylamide slab gels containing 0.1% SDS, as previously described[13]. Markers used to calibrate the gels included myosin (200,000), phosphorylase (91,000), bovine serum albumin (68,000), catalase (60,000), tubulin (55,000) and globin (15,500). 1, 3 and 5 are microtubules purified from 5-d-old rat brains and 2, 4 and 6 are from 30-d-old rat brains.

Our finding that extracts from young rat brains which do not display ring formations polymerise in the presence of glycerol, to yield microtubules similar to those of adult rat brain extracts in which the rings are abundant raises questions as to the validity of extrapolation of *in vitro* studies to the *in vivo* mechanism. Involvement of a membrane-bound initiator protein, with a function similar to that of α-actinin in actin polymerisation, cannot yet be discounted. Such a mechanism could explain the exclusive localisation of microtubules in the growing neurites of the nerve cell.

Tubulin hoops

CYTOPLASMIC tubulin displays a wide range of polymorphism, including small sheets[1] and rings or spirals[2]. We report here several new structures. One of the most interesting aggregates is a hoop which has a triplet substructure and arrangement of the tubulin dimer, similar to that found in flagellar B tubules.

Tubulin hoops were formed by polymerisation of purified protein in the conditions listed in the legend to Fig. 1. Initially, the preparation contained narrow, long, wavy sheets (about 3–7 protofilaments wide). If allowed to polymerise further, the sheets became wider (between 10 and 15 protofilaments) and straightened out. They sometimes folded into microtubules (13 protofilaments) or associated laterally with other sheets oppositely oriented; other sheets folded into small tubules (8–11 protofilaments). Narrow sheets often curled into hoops of 1,000–1,400 nm in circumference. The hoops are thus shallow spirals, and these grew up to widths of 400 nm (about 80 protofilaments). Depending on how they settled down on the carbon film, different images were obtained (Figs 1, 2).

The outside of the protofilaments in the hoops corresponds to the inside of the protofilaments in microtubules. This is evident from Fig. 2*b*, where the inner portions of a hoop lie flat on the carbon film, but adjacent stretches do not fold over properly, as in Fig. 2*a*. The resulting stress leads to breaks or distortions at the corners on the inner side, while the outer rim stays elevated, as verified using platinum shadowed specimens. These images indicate that the outside of the hoop lies on the grid; and by correlating the observed striations with those of the left-handed microtubule helix[3], we deduce that the protofilaments in the hoop are turned inside out relative to the microtubule.

Optical diffraction patterns of the hoop images are best understood in terms of the surface lattice of microtubules[4] or sheets[1]. In Fig. 3*a* the lines connecting the lattice points apply to a microtubule viewed from the front; the back would have the same spacings, but opposite inclinations. The diffraction spots expected from this lattice are asymmetric with respect to the vertical axis if we see either front or back (for example, in sheets, or hoops opened up on the microscope grid (Fig. 2*a*)), and symmetric when front and back are superimposed, such as in microtubules or hoops viewed from the side (Fig. 1).

Some immediate inferences from optical diffraction patterns are that the hoop side view (Fig. 1) is a two-layered structure showing front and back (spots symmetric about the meridian), that the top views are one layered (asymmetric spots), and that adjacent stretches in a proper top view face opposite ways (Fig. 2*a*), but in the same direction in a partial top view (Fig. 2*b*). The spacing of the first layer line is highly reproducible (within 1%), $c = 4$ nm in all our polymorphic aggregates, showing the protofilaments to be connected longitudinally along nearly invariant bonds[5]. The lateral separation between protofilaments varies in the hoops but averages 4.7 nm; this corresponds to the separation of the protofilaments near the

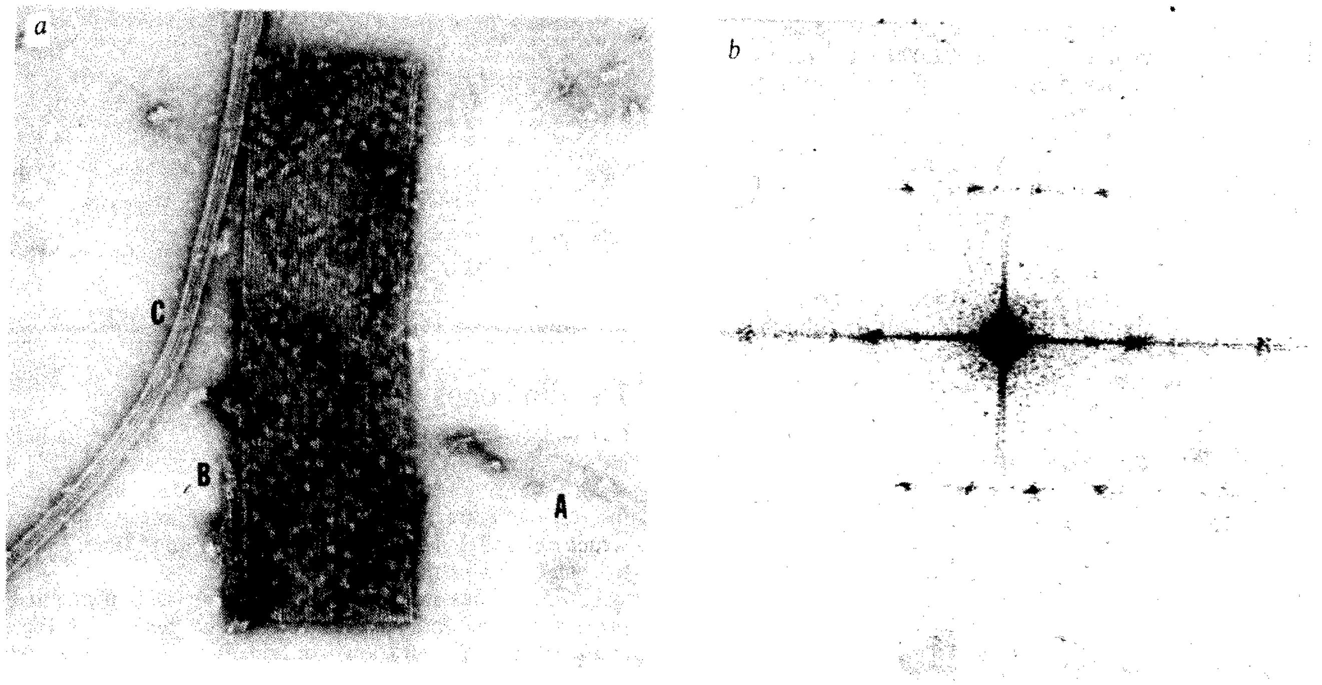

Fig. 1 *a*, Hoop viewed from the side, containing about 40 protofilaments. The probable parent sheet is seen at A, the growth point protruding from the hoop at B. C is a minitubule made from nine protofilaments (× 140,000) Tubulin, prepared essentially according to Shelanski *et al.*[11], was purified by three cycles of polymerisation in reassembly buffer (0.1 M MES, 1 mM EGTA, 1 mM GTP, 1 mM DTT, 0.5 mM $MgCl_2$, *p*H 6.5 at 4 °C) with the addition of 25% glycerol. The protein (5–10 mg ml^{-1} in cold reassembly buffer), was diluted to 1 mg ml^{-1} or less, by adding warm (25 °C, *p*H 6.5, 10–25% glycerol) buffer. After 1–2 min the temperature was raised to 37 °C and polymerisation followed for up to 1 h. Samples for electron microscopy were removed at various intervals, placed on carbon support grids, stained with 1% uranylformate, and examined in a Philips EM 301 electron microscope. Conditions for minimising electron dose were as described elsewhere[12]. *b*, Diffraction pattern of (a). The strong spots on the equator (using the notation of Fig. 3) are the (13, 1) at a spacing of 4.8 nm and (26, 1) at 2.4 nm. Ghost reflections arising from tipling occur at orders of 14.2 nm out to a resolution of 2 nm. The 4-nm layer line is dominated by 4 spots symmetric about the meridian, pairs of (−3, 1) and (10, 1) reflections from front and back, with weak ghosts in between. The 2-nm layer line shows a pair of spots, index (7, 2). Very weak reflections on the 8-nm layer line lie midway between the origin and the (−3, 1) spots. This shows that the arrangement of dimers in the hoops is similar to that in flagellar B subfibres (see text).

centre of the microtubule wall[6]. The shift between adjacent protofilaments also varies and is usually greater than 0.9 nm. Thus, in most cases, 13 adjacent protofilaments cannot be wrapped into a closed microtubule, as is possible with Erickson's sheets[1]. The surface lattice does, however, often fit one of the minitubules mentioned above.

A striking aspect of the images is the periodic tripling of protofilaments. Correspondingly, optical diffraction

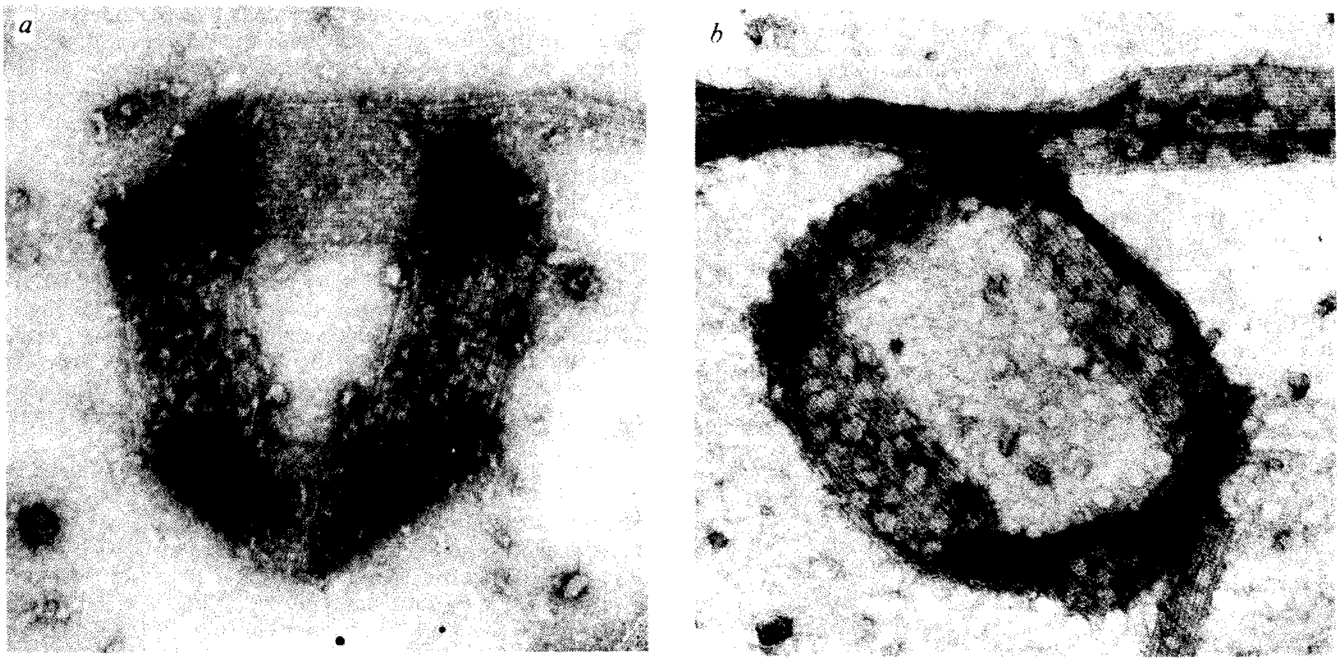

Fig. 2 *a*, Hoop opened up with all sides flattened on the grid. Adjacent stretches are alternating up and down (× 140,000). *b*, Hoop with adjacent stretches facing the same way up. The outer rim is folded over, away from the grid, as established by platinum shadowed specimens. From the inclinations of the (−3, 1) striations it follows that the outside of the hoop, which faces the carbon, corresponds to the inside of the microtubules. This conclusion is supported by the fact that the (−3, 1) striations in the hoop and those in the adjacent sheet which is folding into a tubule, are of opposite inclinations (× 140,000).

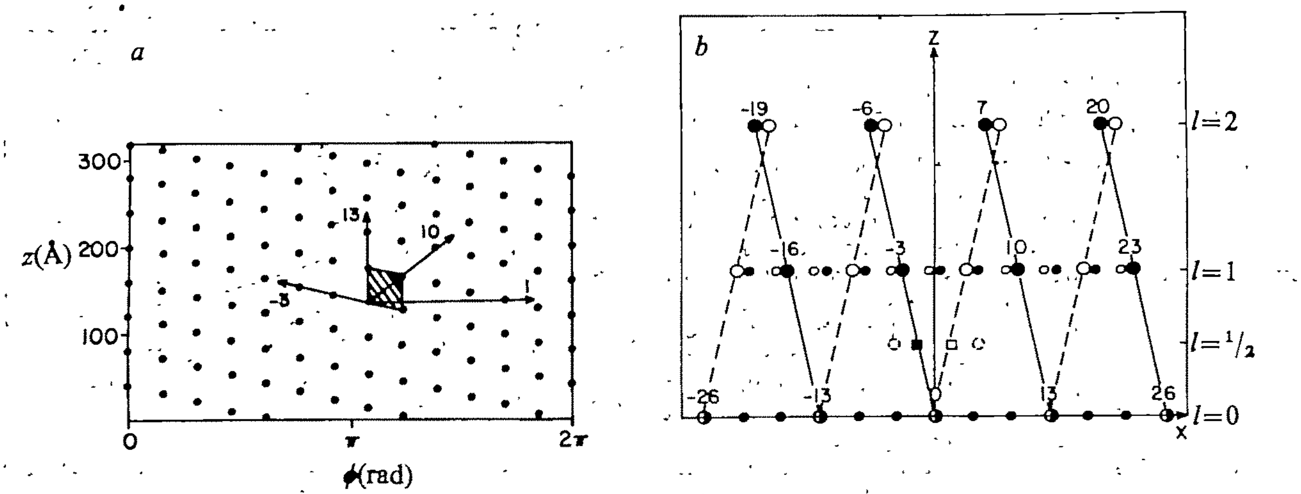

Fig. 3 *a* Microtubule surface lattice according to Amos and Klug[4] as viewed from outside. Directions of main helical families are indicated. There are 13 vertical protofilaments, staggered by 0.9 nm to produce a left-handed 3-start or a right-handed 10-start helix. The 1-start genetic helix does not connect adjacent subunits, so is of no physical significance. Area of unit cell is shaded. *b*, Diffraction pattern expected for flat (two-dimensional) sheets of protofilaments. Microtubule helix nomenclature is used to characterise the diffraction spots: (n, l) refers to the number of helices in a given family, l is the layer line indicating their vertical separation, c/l (c = 4 nm). The equatorial spot (13, 0) comes from the lateral separation of protofilaments; (26, 0) is the second order showing a deepening of the groove and/or a protofilament splitting[1,8]. The (−3, 1) spot on the first layer line arises from the shallow left-handed 3-start helix which is relatively enhanced in electron images, while the (10, 1) spot corresponds to the steeper 10-start helix dominating the X-ray pattern. Open and filled circles correspond to the sheet facing up or down. The spacings of spots in the two lattices (solid and dotted lines) are the same, but inclinations are symmetric about the meridian (Z-axis). Sheets or hoop top views have either open or filled reflections, hoop side views have both. On the equator (l = 0) both lattices are superimposed. The ghost reflections arising from tripling are indicated only on the equator and the first layer line. Numbers refer to the rotational symmetry n of the corresponding structural feature in the microtubule. The quadratic spots on l = 1/2 indicate the B-type superlattice found in hoops; the dotted circles show the positions expected for an A-type bonding (not observed). Hoops are wound up from shallow spirals of parent sheets so that in side views the solid and dotted lattices are slightly rotated (1–2°) with respect to one another.

patterns show a series of ghost reflections dividing the space between main spots into three parts along the horizontal direction (Fig. 1*b*). Hoops smaller than about 10 protofilaments do not show tripling in a systematic manner, nor do the sheets, although some separation into triplets can occasionally be found. In particular, parent sheets forming hoops usually contain between three and seven protofilaments, not only three or multiples thereof. Tripling thus seems to represent an inherent bonding property of cytoplasmic tubulin.

The physical basis for tripling is not known. Flagellar outer doublet microtubules have a partition wall between A and B tubules consisting of three protofilaments of particular stability[7]. Their coherence is attributed to extra protein components[8]. It is possible that even cytoplasmic tubulin has some propensity to form a 'partition wall'. A second inference comes from duplex tubules[9]; that is, cytoplasmic microtubules coated with an outer layer of protofilaments running along a flat helix. The diffraction pattern shows a 15-nm layer line which could mean that the duplex helix repeats after three turns or that the turns are grouped together in threes.

Another unusual bonding property of the hoops is indicated by a very weak 8-nm layer line (Fig. 1*b*). In their analysis of flagellar microtubules, Amos and Klug[4] derive two different surface lattices for the positions of α-β-heterodimers. In both cases the dimers are assumed to lie along the protofilaments ($\alpha\beta\alpha\beta$ . . .). Outer doublet A tubules have alternating subunits along the 3-start helices ($\alpha\beta\alpha\beta$ . . .). Thus along the 10-start helices the bonding is either ($\alpha\alpha\alpha$ . . .) or ($\beta\beta\beta$ . . .). For the incomplete B tubules the reverse holds true. These structures are distinguished by the positions of reflections on the 8-mm layer line (Fig. 3*b*). This analysis suggests that the arrangement of dimers in the hoops is similar to that in the flagellar B subfibres.

Identical bonding of dimers, assuming a 13-protofilament microtubule[10] is possible only with the A-type subunit arrangement. Symmetry arguments therefore suggest that cytoplasmic microtubules have A-type bonding. But, the B-type packing observed with hoops, if present in microtubules, would imply non-identical bonding of subunits. X-ray patterns from microtubules support this possibility[6]. Thus, both the tripling of protofilaments and the B-type lattice in the hoopes suggests a close relation between cytoplasmic and flagellar tubulins.

These studies were undertaken to obtain large, well ordered aggregates of tubulin to aid in the interpretation of X-ray patterns[6]. The hoops contain many unit cells (up to 20,000), and even when negatively stained, their diffraction patterns usually extend to the second and occasionally to the third layer line. This should make them useful in extending the resolution of the existing microtubule model.

Part of this work was carried out at the MRC Laboratory of Molecular Biology, Cambridge. We thank Drs H. E. Huxley, A. Klug and K. C. Holmes, for their interest and discussions. Comparison of bacterial and animal rhodopsins by hydrogen exchange studies

RHODOPSIN is deeply embedded in a hydrocarbon membrane, yet hydrogen exchange (HX) studies show that about 70% of its peptide hydrogens are freely exposed to solvent water[1]. This contrasts with other membrane-bound proteins and even aqueous proteins which generally involve about 70% of their peptide hydrogens in internal H-bonding. It has been suggested that the large fraction of disordered polypeptide chain indicated for rhodopsin resides in and acts to stabilise a channel of water penetrating into the membrane, and further that this channel must be quite large, perhaps 12 Å or more in diameter[1]. Unwin and Henderson[2] described an electron diffraction model for the purple membrane protein of *Halobacterium halobium* (bacteriorhodopsin) which compares interestingly with the suggested structure of animal rhodopsin; membrane-embedded bacteriorhodopsin is arranged in a three-molecule circle surrounding an open space 20 Å in diameter. This space, however, is filled not with water but with lipid, and the protein walls of this blind channel are formed of a double rank of α helices which account for most of the bacteriorhodopsin polypeptide chain, so that bacteriorhodopsin, unlike animal rhodopsin, must be as extensively H-bonded as is the usual protein. We report here a HX study of bacteriorhodopsin. In agreement with the electron diffraction model, our HX results show that this protein, unlike animal rhodopsin, has about 75% of its peptides internally H-bonded. These and previous results, however, suggest a fundamental structural similarity between the two rhodopsins.

HX curves for bacteriorhodopsin in purple membrane are shown in Fig. 1. The slowly exchanging hydrogens measured come from internally H-bonded peptide groups of the membrane-bound protein (for discussion see ref. 1) To measure these, they were initially labelled, before the exchange-out experiment started, by incubating membrane suspensions in tritiated water for long periods at high *p*H to promote fast exchange Exchange of the slow hydrogens that contribute to Fig. 1 was not characterised in any detail because we are more interested at this stage in the number of freely exposed peptide hydrogens in bacteriorhodopsin in order to compare this with the diffraction model and with animal rhodopsin.

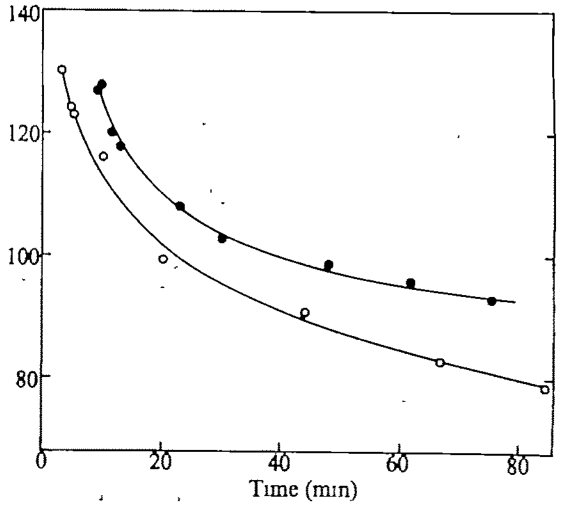

Fig. 1 Hydrogen–tritium exchange-out data for purple membrane suspensions at *p*H 5.0 (○) and *p*H 4.7 (●). The bacteria were grown and the membranes were isolated according to Osterhelt and Stoeckenius[10]. After exchange-in at *p*H 10.5 (2 mM alanine buffer) for 5 d at 4 °C, the purple membrane suspension was adjusted to the appropriate *p*H and passed through a medium Sephadex-G25 column (at low hydrostatic pressure; 0 °C; *p*H 5.0, 10 mM cacodylate or *p*H 4.7, 5 mM citrate) to remove free tritiated water and initiate exchange-out. HX methods were detailed elsewhere[11]. Two to three drop fractions collected from the final columns were diluted to 0.5 ml with 0.1 M phosphate buffer at *p*H 7.4, and maintained at 0 °C in order to measure absorbance. (Absorbance measurements decrease slowly with time at room temperature and are slightly dependent upon *p*H and salt concentration.) Protein concentration in the samples was then computed using a molar extinction coefficient of 7.2×10^4 at 570 nm, determined using the retinaloxime method of Wald and Brown[12] and the thiobarbituric acid method of Futterman[13]. (Total range on 4 preparations was $7.0–7.5\times10^4$.) Bound tritium in the samples was assayed by liquid scintillation counting. These data were used to compute the number of hydrogens per molecule still unexchanged as a function of exchange-out time.

To measure the faster exchanging, freely exposed peptide hydrogens, the earliest part of the curves in Fig. 1 must be studied. It is difficult to measure with good resolution these faster hydrogens above the large background of slow hydrogens High resolution can be achieved by use of a limited exchange-in manipulation, described before (for example, ref. 3), which suppresses the background of slow hydrogens. Samples at *p*H 5 and 0 °C, where the free peptide half-time is close to 1 min, were initially exchanged-in for only 5 min, then quickly passed through a Sephadex column to terminate labelling and initiate exchange-out. This limited incubation period labels all the free peptides but only a greatly reduced number of the more slowly exchanging sites. The measured exchange-out data for the partially labelled protein (Fig. 2*a*) are fitted by a fast phase with the expected free peptide half-time and a slower phase with no predetermined parameters. The isolated fast phase is shown in Fig. 2*b*. Essentially the same procedure was repeated at *p*H 4.7 where peptide HX rate is twofold slower (Fig. 3). In both cases the data indicate ~ 50 hydrogens per molecule exchanging at the expected free peptide rate. One can add 10 prolines to the unbonded residues. These amount to 25% of the total of 242 peptide groups[4] in the molecule. This value is in line with the small fraction of free peptide hydrogens generally seen in other proteins and is consistent with the small fraction expected from the Unwin–Henderson model[2], but it is very different from the value of ~70% free peptides found for animal rhodopsin

The total number of hydrogens measured in these experiments can be obtained with best accuracy by considering Figs 1 and 2 together. Figure 2*a* gives the number that exchange in 5 min at *p*H 5.0 (since initial exchange-in time was 5 min) The number of hydrogens that exchange between 5 min (*p*H 5) and very much longer times can be obtained from the 5-min point on the *p*H 5.0 curve of

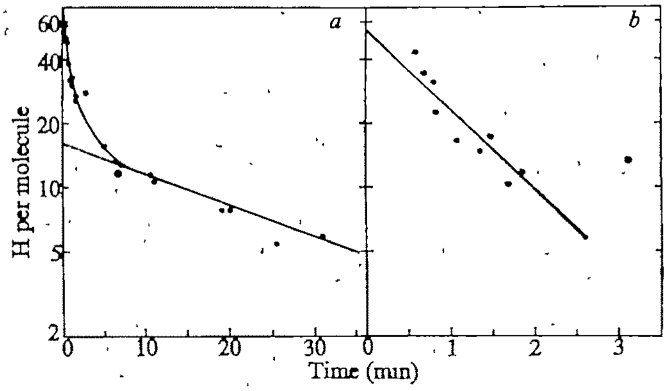

Fig. 2 Limited exchange-in/exchange-out data at *p*H 5.0 and 0 °C. Purple membrane suspensions were labelled at 0 °C for only 5 min at *p*H 5 (10 mM cacodylate) and then passed quickly through a Sephadex column to initiate exchange-out. A semilog plot of the resulting data is given in *a* and the isolated free peptide phase, obtained by subtracting the slow phase from the early time data, is in *b*.

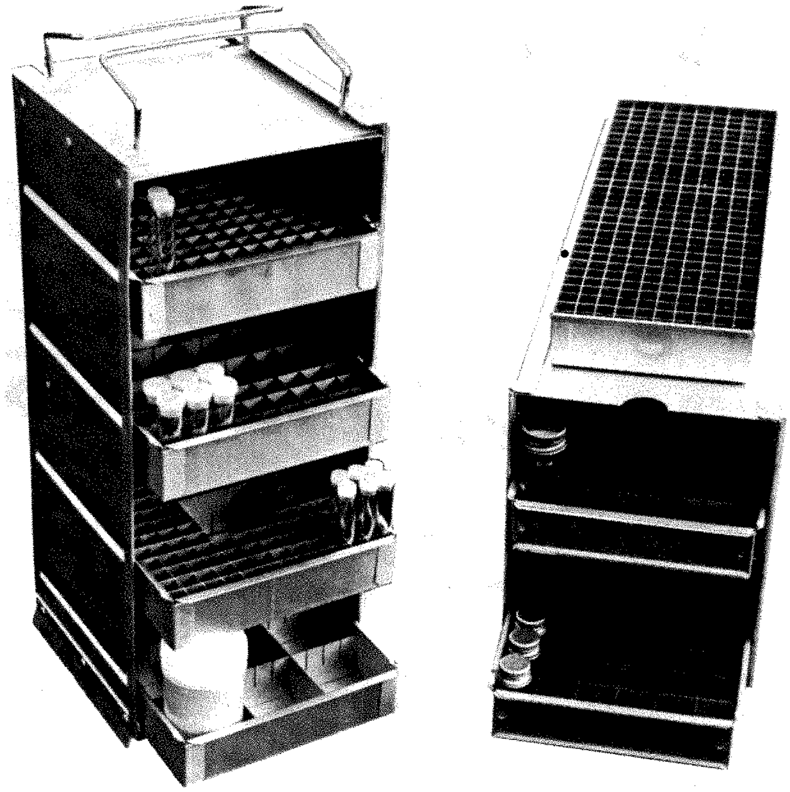
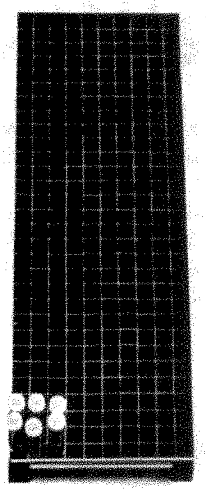
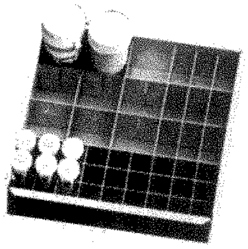
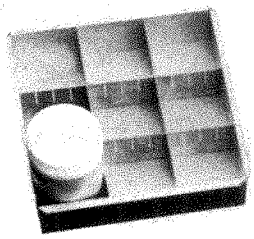
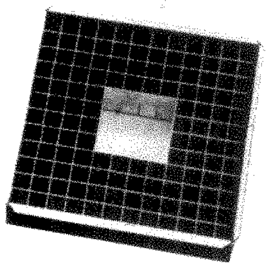
ADDING A NEW DIMENSION TO LUCKHAM LAB TRAYS... AND FREEZFILES.











Luckham Ltd. are now manufacturing a divisible tray system that can be adapted to hold many different sizes of test tubes and bottles. The aluminium divisions for the trays are made so that they simply interlock into a variety of sizes. They also add a new dimension to the Luckham Freezfile System and are ideal for storage, so that your valuable space can be used to the maximum.

The illustrations show a few examples of the many applications possible.

For full information please write or telephone:

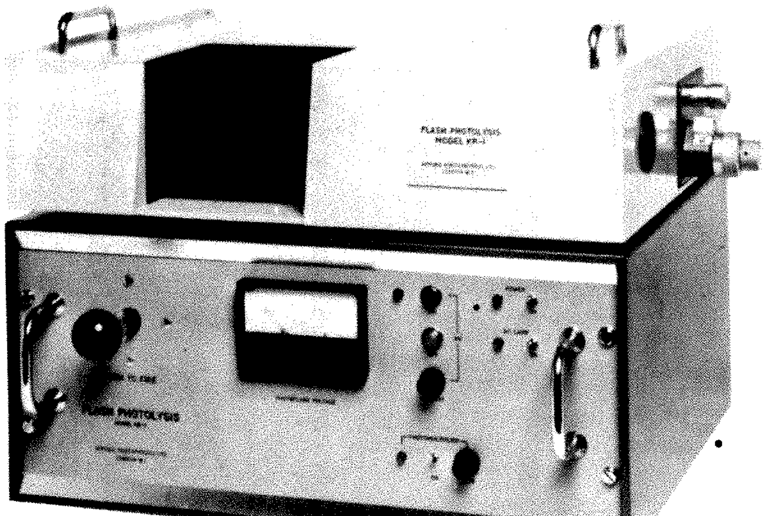
STOPPED FLOW SPECTROPHOTOMETRY

Supplied complete with operating manual and test instructions, this new robust low cost design comprises an efficient mixer with 8 tangential jets, optional hydraulic or pneumatic drive mechanism, and a completely inert glass-fluorocarbon flow line. Dead time is less than 2 milliseconds. The volumes of reagents needed to fill the flow line are very small (less than 3ml of each reagent is sufficient for more than 6 runs) and the apparatus is highly suitable for enzyme studies or work with limited amounts of material. There is provision for accurate temperature control (±0.1K) and additional provision for fluorescence work.

FAST REACTION APPARATUS

FLASH KINETIC SPECTROPHOTOMETRY



Model KR1 is a low cost flash kinetic spectrophotometer for measuring transient decay kinetics. It has a time resolution and sensitivity suitable for most research applications as well as for experiments in a teaching laboratory. The instrument uses two fast flash lamps dissipating a maximum of 200 joules and incorporating a wide range monochromator. Transient species which have moderate to strong absorptions in the region of 330–680mm and have lifetimes longer than 10 microseconds may be studied with this instrument.

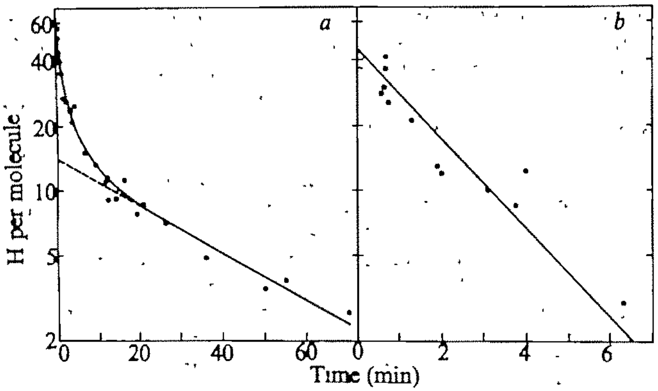

Fig. 3 Limited exchange-out data at pH 4.7 and 0 °C. Exchange-in was for 10 min at pH 4.7 (5 mM citrate) and subsequent treatment was as for Fig. 2.

Fig. 1. The sum of the faster and the slower hydrogens then yields the total number. Similarly, an independent estimate can be obtained from the pH 4.7 data (Figs 1 and 3a). The total number found, ~190 per bacteriorhodopsin molecule, is significantly lower even than the total number of amide hydrogens present (232 peptide H plus from 0 to 64 side chain amide H[4,5]; degree of amidation in unknown). In similar studies with other proteins including membrane-bound animal rhodopsin, the number of hydrogens measured was experimentally identical with the number of amide hydrogens present. The resistant sites in bacteriorhodopsin which could not be labelled by the rigorous exchange-in conditions used here seem to carry the most slowly exchanging peptide hydrogens as yet indicated for any protein, with an exchange rate slower than the expected free peptide rate by a factor of 10^{10} or more. In view of the structure and placement of bacteriorhodopsin, this result is perhaps not too surprising.

These results indicate that bacteriorhodopsin has about 60 free peptides and therefore 180 internally H-bonded ones. This compares with the minimum number of 150 peptide H-bonds required by the Unwin–Henderson model[2] (to generate seven helices of seven turns each with the final turn non-bonded). Previous results[1] show the larger animal rhodopsin molecule to have about 100 H-bonded peptides, and just over 200 free peptides.

Some similarities between bacterial and animal rhodopsins have been pointed out by Osterhelt and Stoeckenius[5], including the use of a *cis*-retinaldehyde as a chromophore, the retinal to lysine Schiff-base linkage, and the effect of the protein on the retinal spectrum and on its chemical accessibility. Further, there is evidence that animal rhodopsin, like bacteriorhodopsin, has a quantity of α helix oriented predominantly normal to the membrane surface[7], and there is the suggestion that animal rhodopsin, like bacteriorhodopsin, may exist as aggregates of several monomers[8]. HX results point to another mild coincidence; though animal rhodopsin is considerably larger than bacteriorhodopsin, the extra length of polypeptide chain in animal rhodopsin has no regular secondary structure so that the structured regions of these two proteins are of roughly comparable size.

Considering possible relatedness of these proteins, it is interesting to examine the bacteriorhodopsin model for clues to the structure and perhaps the function of animal rhodopsin. We note the coincidence involving the previously suggested large channel in animal rhodopsin and the 20-Å 'channel' found in bacteriorhodopsin. While the channel in bacteriorhodopsin is filled in, with lipid[2], it has been suggested that animal rhodopsin maintains a functionally permeable channel by placing many of its extra amino acid residues within the channel with peptide groups exposed to maintain a polar milieu, therefore an aqueous filling[1]. The apparent structural similarities mentioned above suggest a supporting structural framework like that in bacteriorhodopsin for the maintenance of the channel in animal rhodopsin.

We acknowledge gifts of *H. halobium* strains from Paul Mueller and Richard Henderson, and a purified purple membrane preparation from T. Yamane. This work was supported by a grant from the NIH.

Time-resolved resonance Raman spectroscopy of bacteriorhodopsin

BACTERIORHODOPSIN is found in purple patches on the cell membrane of halophilic bacteria[1]. Similar in structure to rhodopsin (but differing in function), it consists of a retinal–protein complex. Bacteriorhodopsin is a photosynthetic system which, when it absorbs light, passes through a cycle of several intermediates (Fig. 1) approximately 200 times per second, pumping protons from the inside of the bacterial cell to the outside. The resultant electrochemical gradient drives the phosphorylation of ADP to ATP (ref. 1). The intermediates have been identified by measuring their relatively broad structureless optical absorption spectra[2–4] as a function of time after a photolytic flash. The most precise structural information has come from resonance Raman spectra[5–8] taken with continuous wave (cw) optical excitation. These studies have

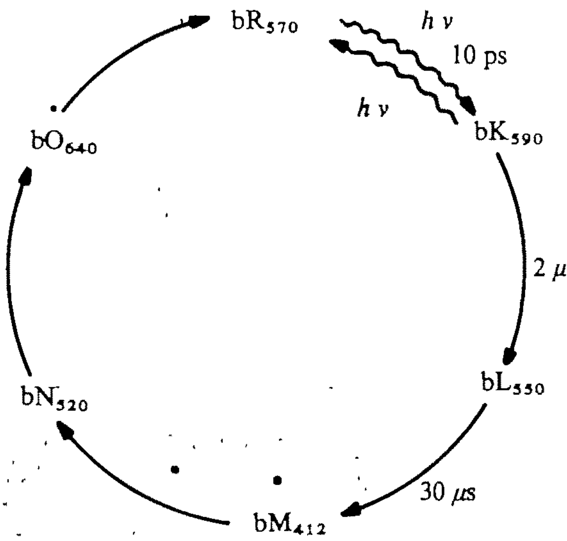

Fig. 1 Photochemical cycle of bacteriorhodopsin (see refs 2–4). Subscripts refer to the optical absorption maxima of each species (nm). Approximate half times are given for room temperature. One cycle is completed in several milliseconds.

provided information about the bR_{570} and bM_{412} intermediates only, since they have appreciable steady state concentrations at room temperature under constant illumination. Resonance Raman spectra of these species have also been obtained at liquid N_2 temperatures and in ether saturated solutions. These conditions, however, may not be representative of actual physiological conditions. We report here a time-resolved resonance Raman spectrum of an intermediate with a risetime of < 6 ns. Our data show a decrease in the C = C stretching frequency by 10–20 cm^{-1}. From the known inverse correlation between the C = C stretching frequency and the position of the absorption maxima[7] for a series of model retinal Schiff bases in various solvents[8], the observed C = C Raman band was assigned to the bK_{590} intermediate, which is known to have a risetime of 10 ps[4].

Time-resolved resonance Raman spectra of bacteriorhodopsin were obtained using a nitrogen pumped tunable dye laser (100-kW 5-ns pulses) at various excitation wavelengths near the maximum of the action spectrum of bacteriorhodopsin[10]. The gated detection system involved a PAR optical multichannel analyser coupled to low (15 cm^{-1}) and moderate (3 cm^{-1}) resolution monochromators using Corning cutoff filters to eliminate scattered radiation at the laser frequency.

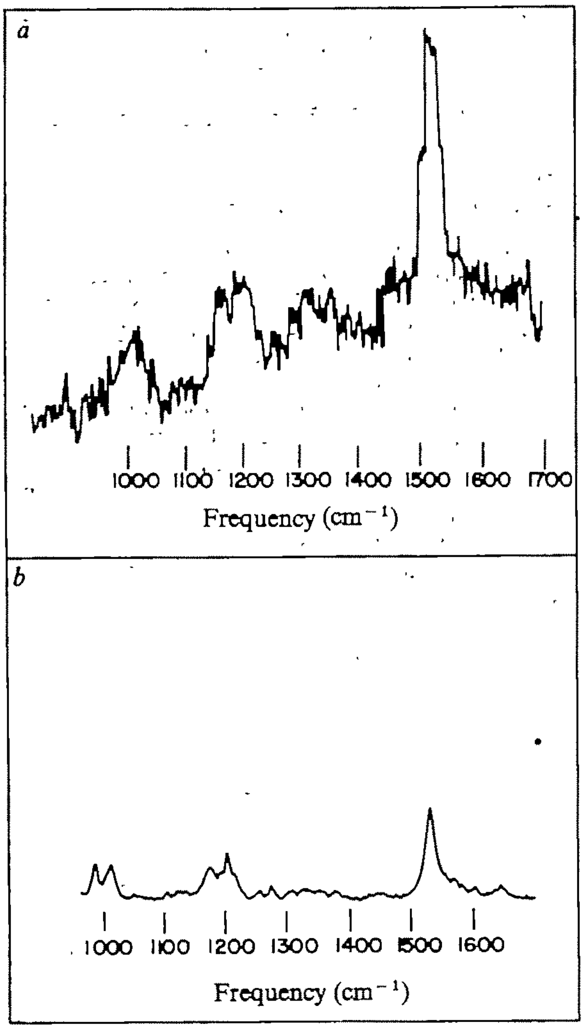

Fig. 2 *a*, Time-resolved (pulse-excited) and *b*, cw resonance Raman spectra of bacteriorhodopsin. The purple membrane fragments were extracted from *Halobacterium halobium* S-9 by the method of Becher and Cassim[11] and suspended in 4.3 M NaCl and 0.5 M $MgSO_4$ at concentrations of 60–100 μM. The time-resolved spectrum was obtained with 5480-Å excitation with a peak power of 100 kW (average power 10 mW) from a Molectron pulsed tunable dye laser. The cw spectrum was excited with 200 mW of cw 5145-Å excitation from a Spectra Physics Model 165 argon ion laser.

The low resolution spectrum with 5,480-Å pulsed excitation is shown in Fig. 2*a*. The prominent features are bands at 1,010, 1,210 and 1,530 cm^{-1}. The spectrum can be compared with a spectrum of bacteriorhodopsin taken with the continuous 5,145-Å line of an argon ion laser (Fig. 2*b*). This spectrum agrees in all respects with those previously reported in the literature[5–8] for bacteriorhodopsin. Considering the lower resolution of the pulse-excited spectrum, the close resemblance of these two spectra confirms that we observed the resonance Raman spectrum of bacteriorhodopsin with a pulsed ns source.

The 1,529 (±3) cm^{-1} band ($\nu_{C=C}$) in the pulse-excited spectrum was asymmetric in the low resolution experiment, so we recorded its band shape under higher resolution. The trace in Fig. 3*a* was obtained at an instrumental resolution of 3 cm^{-1} with the pulsed laser at 5,821 Å. The asymmetry evident in the low resolution scan is revealed to be a shoulder at ~ 10 cm^{-1} to lower energy than the main band which occurs at 1,528 cm^{-1}. The shoulder does not appear in any spectrum[5–8] taken with continuous excitation, regardless of excitation wavelength. The shape of the 1,530-cm^{-1} band measured with the 5,145-Å argon line is evident in Fig. 3*b*. Thus the shoulder seems to be due to the use of a pulsed excitation source.

We have ruled out the possibility that the shoulder is a trivial experimental artefact due to the presence of structure in the background (scattered laser light and fluorescence), by separately varying the wavelengths of excitation and position of the peak on the vidicon target. Both position and intensity with respect to the main peak were reproducible in these varying conditions. Comparison of spectra taken before and after prolonged irradiation by the pulsed laser showed no change in the relative position or intensity of the shoulder, eliminating a permanent photoproduct generated by the high intensity pulse as the species responsible for the shoulder.

We interpret this feature as arising from Raman scattering by the first intermediate in the photochemical cycle, bK_{590}. The repetition rate of the experiement (30 Hz) is much slower than the frequency of the photochemical cycle of bacteriorhodopsin (200 Hz) and thus prevents the formation of any appreciable steady-state concentration of the intermediates in the cycle. Optical absorption measurements have shown that the bK_{590} intermediate is generated in approximately 10 ps[4] and has a lifetime of 2 μs (ref. 2) at room temperature. Because the duration of the laser pulse is 5 ns, only bR_{570} and bK_{590} could contribute to the Raman spectrum. In addition, it has been shown[12] using optical absorption spectroscopy that the photoreaction $bR_{570} \rightarrow bK_{590}$ is photoreversible and that a photostationary state can be established during a 40-ns pulse with peak powers above several hundred kW. The relative concentration of bK_{590} and bR_{570} in this stationary state is 0.4. The intensity of the shoulder in our spectrum is approximately 0.4 that of the main peak at comparable (~ 100 kW) laser power and on a similar time scale.

The frequency difference between the peak and shoulder is consistent both in sign and magnitude with the correlations between optical absorption band maxima and vibrational frequencies reported for model retinal Schiff bases[8]. A 20-nm shift to the red of the absorption maximum of the chromophore would result in a 10–15 cm^{-1} decrease in the C = C stretching frequency, which is consistent with our data.

Our interpretation of this new feature is consistent with predictions from previous data on the lifetime and optical absorption spectrum of the bK_{590} species. We feel that we have demonstrated the utility of time-resolved resonance Raman spectroscopy in obtaining structural information about short-lived transients in photobiological cycles. Our experiments were carried out with acceptable, though not excellent signal-to-noise ratios, and we are currently redesigning the detection system for greater resolution and sensitivity. By using two pulsed lasers, one for photolysis and one as a probe beam we should be able to obtain the time-resolved resonance Raman spectra of other intermediates in the cycle. Furthermore,

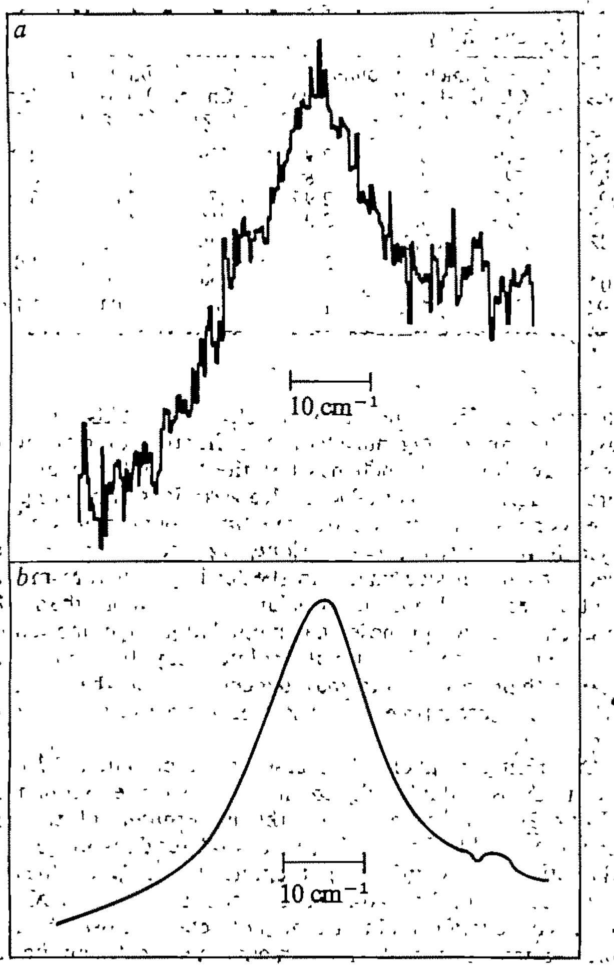

Fig. 3 *a*, Higher resolution of the pulse-excited (time-resolved) resonance Raman spectrum of the 1,530 cm^{-1} band of bacteriorhodopsin excited with 100 kW peak power of 5,821 Å from the pulsed dye laser. *b*, Expanded view of Fig. 2*b* to show the band shape of the 1,530 cm^{-1} peak in the resonance Raman spectrum of bacteriorhodopsin excited with a continuous source at 5,145 Å. The resolution is comparable with that in (*a*).

examination of the other bands in the time-resolved spectra should indicate at which point in the cycle deprotonation of the Schiff base occurs.

We thank Dr M. Nicol and Mr J. Wiget for assistance with the cw Raman spectra, Dr J. Lanyi for *Halobacterium halobium* S-9, Mr R. Sodo for helpful discussion, Mr D. Marvin for reading the manuscript and the ERDA for financial support. A.C. thanks IBM for a predoctoral fellowship.

Novel N-terminal protein blocking group identified as dimethylproline

THE N-terminal region of *Crithidia oncopelti* cytochrome *c*557 could not be characterised by conventional methods because of an apparently blocked amino function[1]. To study this feature the N-terminal tryptic peptide was isolated and 220 MHz proton magnetic resonance (PMR) spectroscopy was used to characterise this peptide and its hydrolysis products. We now report the identification of the novel blocking group as dimethylproline.

The tryptic peptide, known to have the structure X–Pro–$(CH_3)_3$Lys–Ala–Arg (ref. 1) was exposed to thermolysin cleavage to facilitate isolation of X-Pro–$(CH_3)_3$Lys. The trimethyllysine was then quantitatively removed with carboxypeptidase B. Amino acid analysis of X–Pro–$(CH_3)_3$Lys–Ala–Arg showed equimolar quantities of the four amino acids and no anomalous peaks. However, if the acid hydrolysate was separated by electrophoresis at *p*H 2.0 and the paper was sprayed with thymol blue (0.04% in 1 : 1 butanol–ethanol containing 0.01 M H_2SO_4) (ref. 2), an additional band was located which gave no colour with ninhydrin and had a mobility 0.9 that of proline. The indicator dye method depends on the buffering action of carboxyl groups; yellow (alkali) spots are seen on a red (acid) background.

The hydrolysis and electrophoresis was repeated on a preparative scale (3 µmol peptide), the band was eluted from the electrophoresis paper (Whatman 3MM), and the material was passed down a Sephadex G-10 column (100×1.5 cm) in 5% formic acid in order to remove material washed from the paper after electrophoresis. The PMR spectrum of this material is shown in Fig. 1 and the

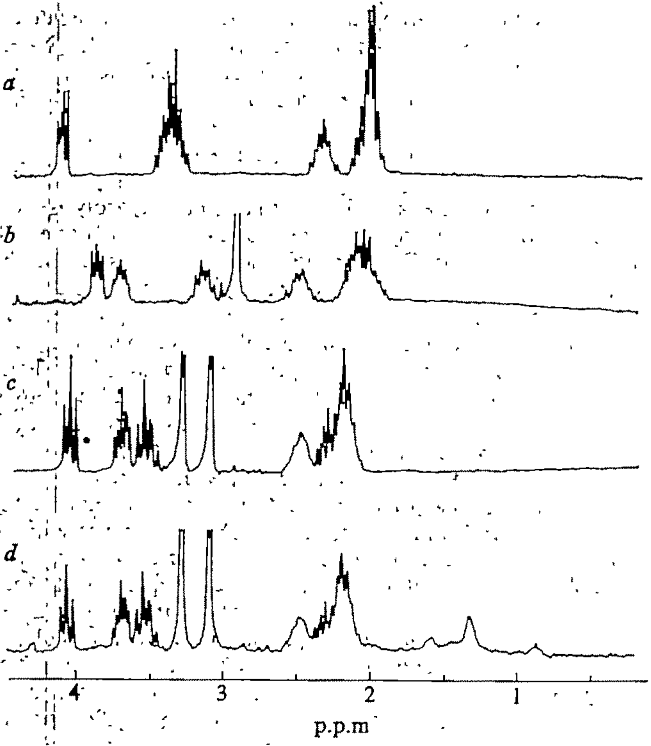

Fig. 1 PMR spectra of: *a*, proline; *b*, monomethylproline; *c*, dimethylproline standard, and *d*, X, isolated from cytochrome *c*557. Solutions were dried in a vacuum from 5% formic acid to remove traces of acetic acid and residues were taken up in 100% D_2O (0.3 ml). Concentrations were approximately 0.5 M for (*a*), (*b*) and (*c*) and 8 mM for (*d*). Spectra were recorded at 22 °C on a Varian HR-220 MHz, instrument modified for pulse Fourier transform operations with equipment supplied by Transform Technology Inc., Chemical shifts were measured relative to internal sodium 2,2-dimethyl-2-silapentane sulphonate.

Areas were normalised to the nearest approximation to integral values.

spectral parameters are summarised in Table 1. Although the spectrum is markedly different from that of proline (Fig. 1*a*), the chemical shifts and areas of the peaks are consistent with a modified proline structure. The two sharp three-proton resonances occur in a region where methyl protons bound to nitrogen are found, suggesting that the material could be *N*,*N*-dimethylproline.

Dimethylproline was synthesised by alkylation of proline (50 mg) with methyl iodide (5 ml) in methanol (5 ml) under reflux. Alkaline *p*H was maintained by periodic addition of methanol saturated with NaOH. The synthetic material was isolated by passage down a Sephadex G-10 column (100×1.5 cm) in 20% acetic acid. It had a mobility on *p*H 2.0 electrophoresis identical to that of the natural material. The PMR spectrum is shown in Fig. 1*c* and summarised in Table 1, where it is compared with that of monomethylproline synthesised according to Bowman and Stroud[3].

It is clear that dimethylproline was present in the acid hydrolysate of the N-terminal peptide. The small amounts of material at 1.3 p.p.m. have been noted with several peptides purified by paper electrophoresis and this material is not completely removed by gel filtration. The evidence is consistent therefore with dimethylproline as the N-terminal blocking group of cytochrome *c*557 and the N-terminal region having the structure.

$(CH_3)_2$Pro–Pro–$(CH_3)_3$Lys–Ala–Arg

There remains the possibility that acid hydrolysis had modified the amino acid of the peptide to give dimethylproline. This possibility could not be investigated by enzymatic digestion as the $(CH_3)_2$Pro–Pro bond was resistant to a wide variety of exo- and endopeptidases. We have therefore examined the problem by comparing the PMR spectra of the natural peptides with that of synthetic dimethylproline. These results, which will be presented elsewhere, are consistent with the presence of dimethylproline in peptide linkage.

Dimethylproline is a novel structure in proteins. It was shown by Vickery[4] to be present in certain plants as the free amino acid and was named stachydrin. It presents an interesting problem in sequence determination and it is possible that it or other α-*N*-methylated amino acids may occur in other proteins. Because the amino group is no longer ionisable in these compounds they are invisible or unreactive using conventional N-terminal methods. The indicator dye method[2] affords a convenient means of visualisation, which was used for the identification of N-terminal amino acids by chemical methylation[2].

The N-terminal region of cytochrome *c*557 is ten residues longer than that of the vertebrate cytochromes *c*. It is possible that this 'tail' and similar 'tails' in plant cytochromes *c* (which are acetylated)[5] and fungal cytochromes *c* (in which the N terminus is free)[6] form relatively free-moving projections from the N-terminal α-helical region common to all cytochromes *c*. Perhaps the susceptibility to methylation of this region in cytochrome *c*557 is due to its detachment from the globular structure. This may also explain why, during purification, a fraction of cytochrome is always isolated which has lost the five N-terminal acids, presumably by a tryptic-like hydrolysis[1]. It is interesting that the lysine residues which are sometimes found methylated in cytochrome *c* sequences, residues 72 and 87 (ref. 7), are very prominent side chains in the tertiary structure models[8] and project out from the globular structure more than other lysines. Thus we propose that methylation of lysine, and in this cytochrome N-terminal proline, may be coincidental rather than specific and may depend only on the extent to which the susceptible group is free from the main protein structure.

A striking parallel to the case of cytochrome *c*577 exists in the myosin alkali light chains that have been sequenced[9]. Frank and Weeds note that the N terminus of the light chain A1 is blocked. This chain is 40 residues longer than the otherwise identical light chain A2; 25% of these 40 residues are proline and the N-terminal region is X–Pro–Lys. The peptide mobilities do not seem consistent with a methylated proline but an N-methylated acidic amino acid does seem a possibility. It would be interesting to re-investigate this region using methods for identifying hydrolysis products with free carboxyl groups.

The proline-rich nature of the N-terminal tail of residues is shared by the plant cytochromes. It is possible that all cytochromes at synthesis contain a proline-rich segment which might be necessary for setting the phase of the N-terminal helix perhaps for folding of the molecule or for the addition of the haem group. This segment may be retained in some and hydrolysed away in others depending on whether blocking of the N terminus had taken place.

Alternatively, a proline-rich segment may be conserved to minimise this very risk that the molecules should be digested by exopeptidases, since proline bonds are notably resistant to many proteases.

We thank Professor M. D. Kamen for his advice and NIH and NSF for grants. We also acknowledge NIH support for NMR facilities.

matters arising

Middle Pleistocene stratigraphy in southern East Anglia

Rose, Allen and Hey[1] proposed a revised chronology for the Middle Pleistocene, based largely on the presence of a rubified sol said to be developed in a temperate climate, but no supporting chemical or palynological evidence was produced.

Extensive surveys conducted by ourselves and colleagues (Institute of Geological Sciences, Geological Survey Sheets 223, 240, 241) have shown that the following sequence of drift deposits is present.

The sequence below is the optimum development but field evidence shows elements of this succession consistently through the area. All these deposits (1–6) are therefore considered to show integral parts of one (Anglian) glacial cycle of events.

Interpretation	Lithological unit
Weathered profile or solifluction deposits	7, Heterogeneous brown flinty sandy clay
Late phase fluvioglacial deposits	6, Poorly sorted sands and gravels
Till, dominantly of the lodgement type	5, Chalky boulder clay variably decalcified at base
Flow till	4, Brown and grey mottled sandy clay with angular and rounded flints, involution structures
Proglacial lake deposits	3, Laminated sands, silts and clay
Proximal outwash braidplain deposits with local flow tills	2, Sands and gravels with localised developments of (4) and (5), including the basal chalky Maldon Till which may be of the lodgement type
Distal outwash deposits	1, Fine micaceous sands

A reddish colouration is developed at a number of horizons particularly where sandy clays have suffered remobilisation or eluviation has taken place from the lowest clay bed in the sequence. The eluviation process was apparently accompanied by dissolution of limestone material from the permeable beds where the ground-water was not lime-saturated. It seems unlikely that each of these horizons could be regarded as indicating a warmer period.

The thin and localised development of the Anglian fluvioglacial deposits suggested by Rose, Allen and Hey[1] is questionable for an area near the margin of an active ice-sheet. There is evidence for the former presence of an active ice sheet in the Thames Estuary[2] area which may have influenced the outwash drainage of the main East Anglian ice and thus account for the deduced north-eastward flow[1] of the lower gravels.

[2] Lake, R. D., Ellison, R. A., Hollyer, S. E. & Simmons, M. *Rep. Inst. geol. Sci. U.K.* (in the press).

Rose, Allen and Hey reply—In response to Lake *et al.*[1] we wish to clarify the following points:

(1) Recognition of the temperate palaeosol is based not only on red colouration but on clay enrichment, iron enrichment, and clay skins on the upper sides of pebbles. These properties are considered characteristic of the illuvial horizon of a *sol lessivé* formed over a long period in a humid warm temperate climate. We are aware that iron stained horizons are common at many levels in the lower sand and gravel unit, but unlike the palaeosols horizon, these levels are not accompanied by a significant clay enrichment or clay skin development, and their colour does not reach levels of redness as high as 2.5 YR or 10 R. These iron-stained horizons are not continuous and are not developed at any particular level, but are specifically associated with sedimentary structures along which ground water drainage has been localised. The properties of the rubified *sol lessivé* are developed independently of the sedimentary structures and the original particle size characteristics.

(2) Lake *et al.* state that "sandy clays have suffered remobilisation, or eluviation has taken place from the lower clay bed in the sequence", to account for the "reddish colouration". If these processes were responsible, however, reddish colouration should be continuous along the interface of the sands and gravels and the overlying till. This is not the case. At certain localities the palaeosols horizon is cut-out by till. At other localities it is overlain by the upper sand and gravel unit and is thus not associated with a 'clay bed'. As the palaeosols horizon is cut-out by glacial and glacifluvial erosion, and as blocks of the palaeosol form erratics in the overlying till, rubification has occurred before ice invaded the locality.

(3) The observation that "the eluvial process was apparently accompanied by dissolution of limestone material from the permeable beds where the groundwater was not saturated" is incorrect, as fresh, hard limestone pebbles have been observed in all parts of the lower sand and gravel unit.

(4) An arctic structure soil is superimposed on the *sol lessivé*. This consists of an horizon of involutions, ice wedge casts, and sand wedges and is associated with coversand, loess, and wind polished stones. This indicates a long period of sub-aerial weathering in addition to the *sol lessivé*, and also demonstrates that the sequence of deposits were not formed in a single "glacial cycle of events".

(5) The revision of the stratigraphy is not solely based on the recognition of the palaeosols horizon. The glacifluvial sands and gravels above the palaeosols can be distinguished from the underlying periglacial river deposits on the basis of particle size, stone content, primary sedimentary structures, secondary sedimentary structures, palaeocurrent directions[3], and heavy mineral assemblage (J. A. Catt, personal communication). The heavy minerals in the lower sand and gravel unit show a restricted residual suite, whereas the range

of heavy minerals in the upper sand and gravel unit is greater and many readily-weatherable minerals are included. This suggests that the heavy minerals in the upper sand and gravel unit have been enriched from a new source, such as would be associated with a glacial event. Also the frequency of volcanic rocks, quartz, and quartzite is much greater in the lower sand and gravel unit than in the till. Thus it is impossible to argue that these materials could have been derived either from the till or from the ice which deposited the till.

(6) We are interested to know on what basis active ice in the Thames would affect outwash drainage as far away as Bury St. Edmunds.

(7) Anglian glacifluvial deposits are restricted because most of the meltwater beneath the ice was concentrated in 'tunnel valleys' related to a low sea level[3]. The relative scarcity of glacifluvial deposits in an ice-marginal location is not peculiar to southern East Anglia. It is also characteristic of the southern margin of the Devensian ice sheet.

The cause of Forbush's 20-year wave

Levy[1] has suggested an explanation of Forbush's[2] 20-yr wave in the galactic cosmic-ray diurnal anisotropy. Levy states he knows of no other way to account for the variation. This note discusses a previously known alternative mechanism and provides a calculation for the thickness of the heliosheath.

Any mechanism to explain Forbush's 20-yr wave must use the 20-yr oscillatory solar cycle vector dipole field (B_{SD}). To obtain a sinusoidal wave from this vector, it is necessary to have a mechanism which basically takes the product of B_{SD} with a stationary vector. Levy's mechanism utilises the azimuthal twisting of the interplanetary magnetic field (IMF) lines to obtain an enhanced radial $\nabla \times B$ drift between the positive and negative field of the extended solar dipole. The azimuthal twisting of the field as a result of the solar rotation is important because the perpendicular drift in a radial field would only result in an azimuthal drift of the cosmic rays[3] with no outward 20-yr wave. Thus Levy's mechanism takes the product between B_{SD} and the angular velocity vector of the Sun to obtain an effect.

Schatten and Wilcox[4], however, take the product between B_{SD} and the nearby galactic magnetic field (GMF) vector to obtain their effect. In this model, cosmic rays either gain access to the heliosphere at high (or low) heliographic latitude depending on whether the extended IMF connects to (or is closed from) the GMF. This causes a 20-yr streaming of cosmic rays away from (or toward) the Sun along the IMF of the type Forbush observes, and Duggal and Pomerantz[5] confirm.

Matters arising

Matters Arising is meant as a vehicle for comment and discussion about papers that appear in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted. Neither contribution nor reply (if one is necessary) should be longer than 300 words and the briefest of replies, to the effect that a point is taken, should be considered.

It is interesting that this latter view, if correct, enables a calculation of the thickness of the heliosheath. The cosmic rays producing the Forbush effect have an energy of around 25 GeV (refs 1 and 2). Thus their rigidity is $R\ \mathrm{V} \doteq 300\, H\rho$ (H in gauss, ρ in cm).

The heliosheath fields are most effective at filtering cosmic rays with gyroradii comparable to the heliosheath thickness $\rho \sim d$. An extension of the Archimedean spiral IMF suggests H may be as low as 6×10^{-7} G whereas the galactic magnetic field is nearer 10^{-6} G (ref. 6). Equating p to d in the above equation, we find for d, a value of 1.4×10^{14} cm $\sim$ 10 a.u. This is in fact approximately the value suggested for the heliosheath thickness[7]. Undoubtedly Pioneer missions to the outer planets may add to our knowledge about what is happening in this interesting region of space.

I thank M. A. Pomerantz for valuable discussions. This research was supported by the Atmospheric Research Section of the National Science Foundation.

Levy replies—The suggestion put forward by Schatten and Wilcox[1], that the solar-magnetic-cycle wave in the diurnal variation of energetic cosmic rays results from alternating connection and disconnection of the interplanetary and galactic magnetic fields, is an interesting one that deserves quantitative discussion. Although this is not the place to discuss the idea in detail, one remark does seem in order.

As I understand Schatten's present calculation, particles with cyclotron radii that are small compared with the characteristic length scales in the magnetic-field reconnection region will efficiently follow the field lines and thus will show the largest effect of field line topology. Particles with increasing energy, and thus increasing cyclotron radii, will be less inhibited in their motion by the details of the filed-line topology in the heliosheath reconnection region. Thus it seems to be a natural consequence of Schatten's and Wilcox's proposal, in its present form, that the amplitude of the variable anisotropy is a monotonically decreasing function of particle energy. The existing, but sparse, information on this point[2] suggests that this is not the case. The amplitude of the varying anisotropy seems to increase with energy in the range below 20–30 GeV and to decrease at larger energies. This behaviour is consistent with that predicted as a result of particle drifts[3] in a large-scale coherent interplanetary magnetic field[4].

Monographs for Students of Medicine
Series Editors: R. J. Harrison and A. W. Asscherr.

Sex and Infertility

R. G. Harrison and C. H. de Boer

March/April 1977, xii + 121pp., £2.80/$5.50 (Paperbound) 0.12.327850.3

Sex and Infertility aims to educate the undergraduate and postgraduate medical student in the problems of the infertile couple, with particular reference to the male. In addition to a description of the clinical features of the infertile couple and the methods of clinical examination, the authors outline the basic anatomy and physiology of sex and the reproductive apparatus as a preliminary to a full understanding of coitus and fertilisation. The book has been designed to aid courses in sex, reproduction and infertility which exist in many medical schools.

Symbols and Sentiments

Cross-cultural Studies in Symbolism

edited by Ioan Lewis

February/March 1977, x + 310pp., £8.50/$16.65 0.12.446650.8

This book is the product of an inter-disciplinary seminar arranged to encourage more fruitful cross-fertilization between social anthropologists, psychiatrists and psychoanalysts. Believing that its chosen theme is of central importance to both disciplines, this symposium addresses the problem of interpreting the emotional as well as the cognitive meaning of symbols. The papers span a rich diversity of cultural and historical settings and take the connection between symbolism and sentiment as their unifying force.

Biochemical Correlates of Brain Structure and Function

edited by A. N. Davison

March/April 1977, xiv + 346pp., £14.00/$27.35 0.12.206650.2

In recent years, with the delineation of the broad principles of intermediary metabolism of the brain and the identification of specific brain constituents, it has been possible to begin the important task of correlating structure and function of the nervous system with its biochemistry. In this collection of studies, neurobiologists from widely different disciplines survey recent research on the biochemical basis of normal brain structure and function, with the emphasis on an interdisciplinary viewpoint. The book falls into three sections: the developing brain; chemical-structural correlations; and the biochemistry of behaviour.

Proceedings of a Symposium Organised by the London Mathematical Society with the Support of the Science Research Council and the Royal Society

Algebraic Number Fields

(L-functions and Galois properties)

edited by A. Frohlich

February/March 1977, x + 704pp., £16.00/$31.25 0.12.268960.7

This volume is the outcome of a research symposium in algebraic number theory, held in September 1975 at the University of Durham, England. Almost all the lectures given are recorded here, and in many cases they have been expanded and new, relevant material added. The specific topic of the symposium was 'L-functions and Galois properties of algebraic number fields' — an area which is currently undergoing exciting, fundamental developments, and the volume reports on these. It contains contributions of an introductory nature, surveys of recent work which has appeared in a variety of technical papers, and also a number of original papers whose contents have not previously been published.

Proceedings of the Second Conference on the Mathematics of Finite Elements and Applications

The Mathematics of Finite Elements and Applications II — MAFELAP 1975

edited by J. R. Whiteman

March/April 1977, xiv + 573pp., £21.00/$41.00 0.12.747252.5

This is the proceedings of the 2nd Conference on the Mathematics of Finite Elements and Applications, held at Brunel University in April 1975. The purpose of the Conference was to bring together mathematicians and engineers whose common interest was finite element methods. The resulting book consists of eleven invited papers and thirty-two short contributed papers, with the invited papers defining the state of the art of finite elements and the contributed papers describing current research. The papers fall into three categories: the mathematics of finite elements; applications; and computational techniques. In this way the book both breaks new ground and is a reference work.

reviews

Adaptation to marine life

R. P. Dales

Adaptation to Environment: Essays on the Physiology of Marine Animals. Edited by R. C. Newell, Pp. 539. (Butterworths: London and Boston, Massachusetts, November 1976.) £25.

THIS book comprises nine separate reviews: Adaptations to intertidal life by the Editor himself; Settlement responses in marine organisms by Professor Crisp; Primitive respiratory mechanisms by C. P. Mangum, Physiological adaptation to life in estuaries by A. P. M. Lockwood; Rhythms, behaviour and reproduction in marine animals by Professor Naylor; Vision in pelagic animals by J. K. Bowmaker; and three chapters by P. W. Hochachka and G. N. Somero: Biochemical adaptations to pressure; Enzyme and metabolic adaptations to low oxygen, and Biochemical adaptations to temperature.

Nine chapters within the compass of over 500 pages has provided each author with sufficient space to review in some detail the current concepts and knowledge in their own field. Any of these reviews might have appeared in either of the volumes of reviews in marine biology currently being published by Academic Press or Allen and Unwin. Such a volume as this may be justified by the amount of work being produced or by the individual contributions making a coherent whole.

It is six years since Newell's book on the *Biology of Intertidal Animals* appeared and so much interesting research has been done since then that in many ways I regret that the field was not restricted to environmental adaptations of intertidal animals. This is not to welcome Bowmaker's contribution on vision for, although this chapter is perhaps the most isolated in subject matter from the others, a review of this subject was much needed. And, although the literature is less extensive than that reviewed elsewhere in the book, the most significant recent papers are not readily available. It is also a more difficult subject for most students, so that it is good to have this literature authoritatively assessed.

This is an invaluable book to all those interested in the adaptation of organisms to their environment. Much of the contents are familiar, but the incorporation of recent work and subsequent discussion is valuable for students and teachers trying to keep up-to-date in this field.

Thus Crisp's review of 1974 is amplified, and Naylor's review of rhythmic behaviour is to be welcomed because it brings together various aspects of the subject such as circadian rhythms, vertical migration and reproductive cycles. Mangum's review also pulls together the many recent contributions in the field of respiratory pigment function. This last is particularly interesting for the comparison of intra- and extracellular respiratory proteins and for her ideas on the evolutionary significance of red cells in invertebrates. Lockwood's chapter on the physiology of estuarine organisms is useful too, not only because it is his own account but because other recent reviews and treatises have been more ecological than physiological in approach.

The three chapters by Hochachka and Somero also bring up-to-date the subjects discussed in their recent book on *Strategies* (Saunders: Philadelphia, 1973), in *Comp. Biochem. Physiol.* and in the Society for Experimental Biology Symposium on *Pressure*, edited by Sleigh and Macdonald. Most of the chapter on low O_2 adaptations will be familiar to those who know *Strategies* but the more recent work done both by Hochachka's own group and by de Zwaan's group in Utrecht on bivalves, is included here.

A most useful series of essays on physiological and biochemical adaptation, well printed and illustrated, a book no zoological library can afford to be without. It is a pity that rising costs puts such a book beyond the reach of most individuals. ☐

R. P. Dales is Professor of Zoology at Bedford College, University of London, UK.

Ion implantation

Ion Implantation of Semiconductors. By G. Carter and W. A. Grant. Pp. viii+214. (Arnold: London, 1976) Boards £9.50; paper £5.95.

ION IMPLANTATION was for a number of years a specialist subject studied only by research scientists and engineers. The past five years has seen the increased acceptance of the technique in the semiconductor device manufacturing industry and a growing awareness of its potential in other areas. It is not surprising, therefore, that a number of educational establishments have introduced courses on the subject. It is clearly intended that this book should provide a student text for such courses. For this purpose the book is well suited.

It guides the reader in a logical manner through the physics of ion implantation. Starting with very elementary concepts, all aspects of the subject are explained. There is an unfortunate over simplification of the theory of ion range calculations. It has been assumed, without apparent justification, that implanted profiles are symmetrical, whereas the physics of observed asymmetric profiles is well understood.

The greatest shortcoming of the book is in the treatment of the electrical effects of ion implantation in semiconductors. Most of the book could be applied equally well to metals and insulators. As it is the electrical effects in semiconductors that have made them of special technological interest it was very disappointing to find that the discussion on this aspect did not merit a chapter on its own but was included in a rather abbreviated devices chapter. This has meant that important topics such as electrical measurements during annealing have been curtailed and the electrical properties of compound semiconductors virtually omitted. It has also meant that some important device application areas such as threshold changing in MOS transistors were not included.

In summary, the book is likely to be useful as a general introduction to the subject but should not be regarded as being specific to semiconductor applications.

B. J. Smith is a member of the research staff at the Atomic Energy Research Establishment, Harwell, UK.

Chemical carcinogens

Chemical Carcinogens. (ACS Monograph 173.) By C. E. Searle. Pp. xxvii + 788. (American Chemical Society: Washington, DC, 1976.) $67.50.

THAT most cancer in man is caused by chemicals is now accepted, although the first demonstration of cancer produced by a pure chemical compound was only published in 1930 as a postscript to a paper by E. L. Kennaway. Before that there was evidence that soot, coal tar, pitch, and some oils caused cancer in man; and soon after Kennaway's successful experiment the widely distributed carcinogen, benzopyrene, was isolated from coal tar and synthesised. These experiments opened the gates to a flood of research in chemical carcinogenesis. Most cancer in man is caused by chemical substances in the environment and a sure way of preventing cancer is to identify these carcinogens and remove them. Such removal is not always feasible in practice. The most ubiquitous cause of cancer in Britain is tobacco but it seems impossible to prevent smoking. The active chemical carcinogen or carcinogens in tobacco smoke are still not known and attempts to make 'safer' cigarettes are hampered by the lack of knowledge.

The existing knowledge of chemical carcinogens and the research in the problems are so vast that it is difficult for individuals or even teams of workers to cover the subject. The volume under review is an admirable and much needed attempt to present the available facts and some of the theories. The main gap in the book is that inorganic carcinogens, except asbestos, are not considered.

The editor points out that this is not the first effort to list a catalogue of chemical carcinogens. The US Department of Health, Education and Welfare has published a series entitled *Survey of Compounds Which Have Been Tested for Carcinogenic Activity,* some of which were edited by Hartwell and Shubik The first of the series appeared in 1951 and the last, which is generally available, includes data published in 1971. The International Agency for Research on Cancer in Lyon has published twelve monographs on the *Evaluation of the Carcinogenic Risk to Man.* These monographs are invaluable to research workers and administrators concerned with cancer problems. In very few cases, however, is it possible to evaluate the potential carcinogenic hazard to man of pure chemical compounds.

In addition to the preface written by the editor, which is an excellent review of the present position of the subject, there are 16 chapters written by 23 experts in their fields. There is less repetition than would be expected with a book written by so many authors. The chapters on "Soots, tars and oils" by Kipling, on "Laboratory hazards" by George and Searle and on "The Bracken Carcinogen" by I. A. Evans and "Asbestos" by Wagner, are each about 10 pages. The chapter on "*N*-Nitroso Compounds" by Magee, Montesano and Preussmann is an authoritative review of the subject covering 125 pages. In the case of this and other articles it would be of value and interest to know when they were written.

There are also comprehensive reviews on endocrine aspects, alkylating agents, polynuclear aromatic carcinogens, environmental respiratory carcinogenesis, aromatic amines, carcinogens in plants and microorganisms, and metabolism of chemical carcinogens.

The book is well produced, easy to handle considering its size, and provides an excellent overview and reference work, although it is already out of date in some minor matters.

E. Boyland

E. Boyland is Visiting Professor in Environmental Toxicology at the School of Hygiene and Tropical Medicine, London, UK.

Perception handbook

Handbook of Perception. Vol 7: Language and Speech. Edited by E. C. Carterette and M. P. Friedman. Pp. xviii + 501. (Academic: New York and London, 1976.) £16.25.

A SUCCESSFUL handbook has the opposite fate to a 'classic': it is consulted, but not quoted. It is used to settle disputes, to aid memory, and to fill in inevitable gaps in knowledge. To these ends it must be well organised, comprehensive, and authoritative. In psychology, the standard was set by S. S. Stevens's *Handbook of Experimental Psychology* which was first published in 1951. Carterette and Friedman are engaged in the publication of a more ambitious work, a ten-volume handbook intended "for all in the arts or sciences . . . who are interested in human perception". The first six volumes are concerned with fundamentals, and the present volume is the first to be devoted to a wider consideration of the contents of perception rather than particular processes or modalities.

There are fourteen chapters arranged in four parts: fundamental aspects of language and speech; coding, perception, and hearing; disorders of language and speech; and trends in psychological tests of linguistic theory. These headings are not auspicious and certainly do not reflect a natural organisation of the field. The assignment of topics to them turns out to be fairly arbitrary, and the problem of finding one's way through the book is further aggravated by a considerable degree of overlap between the contents of the chapters Accounts of the production of speech crop up in three different places, varying considerably in detail, and there are numerous cases of brief descriptions of the same work occurring in more than one chapter—for example, the subjective location of clicks, Katz's theory of semantics, and Winograd's program for understanding natural language.

The book ranges reasonably comprehensively over the major topics in the area, and includes useful chapters on speech perception (C. Darwin), the syntactic analysis of sentences (J. M. Carroll and T. G. Bever), the research methods of psycholinguistics (G. Olson and H. Clark), non-verbal communication (J. Laver), and aphasia (H. Goodglass and N. Geschwind). Somewhat surprisingly, it also has chapters on language teaching and language learning, disorders in speech production, and the general development of language in children. Yet, a number of topics very relevant to perception do not have chapters devoted to them—for example, intonation and tone of voice, the psychology of reading, and computer programs for understanding speech. At a more technical level, the reader will look in vain for an account of linear prediction theory, augmented transition networks, the perception of illocutionary force, and procedural semantics. It is probably no coincidence that each of these topics reflects an increasing concern with psychological processes in real time rather than with the static structures of linguistic theory. Ironically, the chapter that best captures this growing preoccupation, MacNeilage and Ladefoged's excellent discussion of speech production, is concerned with perception in only a tangential way.

In summary, the compilers have solicited a number of authoritative articles from acknowledged experts, but they have failed to cover the field comprehensively and to edit the materials to the best advantage. They have produced a superior symposium rather than an indispensable handbook.

P. N. Johnson-Laird

P. N Johnson-Laird is Reader in Experimental Psychology at the University of Sussex, UK.

Reference books in behavioral, natural and applied sciences...

THE HANDBOOKS OF AGING SERIES
Editor-in-Chief: James E. Birren

Volume 1: Handbook of Aging and the Social Sciences establishes a groundwork for more efficient research into the justification and directions for providing practical services to older adults. 684 pp., illus., $32.50

Volume 2: Handbook of the Psychology of Aging examines changes in behavior and capabilities that occur with advancing age. 740 pp., illus., $32.50

Volume 3: Handbook of the Biology of Aging proceeds from molecular to the cellular, physiological and organismic levels in exploring the varieties of aging changes displayed by humans and other mammalian species. 700 pp., illus., $32.50

THE GIRAFFE
Its Biology, Behavior and Ecology

By Anne Innis Dagg and J. Bristol Foster. This monograph presents enlightening new information on giraffe ecology, behavior, conservation and management. It includes facts on the animal's anatomy, physiology, longevity, reproduction, evolution, subspeciation, herd relationships, population structure, and association with aboriginal and European man. "This book will provide the foundation for any new understanding of this species."—**Science** 224 pp., illus., $13.95

Grzimek's ENCYCLOPEDIA OF EVOLUTION
Editor-in-Chief: Bernhard Grzimek

Tracing the history of life on earth, this single-volume encyclopedia describes evolutionary forces that influenced the development of all animal species, including man. It is based on the work of over 200 international authorities on paleontology and evolutionary biology, reflecting all important theories and techniques in these fields. 560 pp., 1,000 color and monochrome illus., $39.50

Grzimek's ENCYCLOPEDIA OF ECOLOGY
Editor-in-Chief: Bernhard Grzimek

Exploring the interrelationships of animals and man to their environment, this self-contained reference shows how various species have adapted to a vast diversity of habitats. Extensive coverage of the environmental crisis includes destruction of the natural landscape, contamination of the oceans, and noise, air and water pollution. 744 pp., 1,000 color and monochrome illus., $39.50

Grzimek's ENCYCLOPEDIA OF ETHOLOGY
Editor-in-Chief: Bernhard Grzimek

Beginning with extensive background information on animal systems and sense organs, this one-volume encyclopedia examines areas such as learning and communication behavior, courtship and pair-bonding, orientation in time and space, and prenatal and postnatal behavior development. Also covered are the goals and methods of ethological research, and the significance of ethology in understanding human behavior. 600 pp., 100 illus., $39.50

THE CONDENSED CHEMICAL DICTIONARY
Ninth Edition

Revised by Gessner G. Hawley. The new, updated ninth edition marks the entrance of this unique book into its fifty-eighth year of professional service to the chemical and allied industries. It is not a dictionary of brief definitions, but a compendium of technical data and descriptive information covering thousands of chemicals and chemical phenomena, organized to serve the needs of those who have only minutes to devote to any given substance or topic. 1,000 pp., $32.50

All prices subject to change without notice.

WILEY
INTERSCIENCE

FUNDAMENTALS OF ELECTROCHEMICAL ANALYSIS

by **Z. Galus**, *Department of Chemistry, University of Warsaw.* Translation editor: **G. F. Reynolds,** *The Research Laboratory of Instrument Physics, Reading University.*

This book provides a broad coverage of the theoretical principles of almost all methods used in electrochemical analysis. It also contains practical material for making and interpreting electrochemical measurements in analysis, research quality control or advanced study. It concentrates on polarography, stationary electrode voltammetry, chronopotentiometry and rotating disc electrode techniques, and includes cyclic voltage methods, the ring and disc electrode techniques, and most other electroanalytical methods. (Ellis Horwood series in Analytical Chemistry).

538 pages December 1976 $44.65/£23.50

Published by Ellis Horwood Ltd., Chichester, and distributed by John Wiley & Sons Ltd.

PHOTOCHEMISTRY OF HETEROCYCLIC COMPOUNDS

edited by **O. Buchardt,** *University of Copenhagen.*

Essays by specialists in the subject survey the entire field of heterocyclic chemistry.

632 pages August 1976 $59.85/£33.70

CRYOCHEMISTRY

by **M. Moskovits**, and **G. A. Ozin,** *both of University of Toronto.*

Introduces the fundamentals of cryochemistry, focusing on chemical aspects of the subject: synthesis, structure, and reactivity. Presents an up-to-date account of the technology available to the cryochemist and its application in diverse fields.

544 pages December 1976 $39.00/£24.20

TRACE ANALYSIS:
Spectroscopic Methods for Elements

edited by **J. D. Winefordner,** *University of Florida.*

A reference source that provides important information for those involved with trace analysis of elements in real samples. Analytical figures of merit including detection limits, sensitivities, selectivities, precisions, and accuracies are given where possible for each element by each atomic technique: only those techniques that are truly trace analytical methods are dealt with.

496 pages *June 1976* $30.95/£18.45

PROGRESS IN INORGANIC CHEMISTRY Vol. 21

edited by **S. J. Lippard,** *Columbia University.*

This volume of the series continues the authoritative forum for critical evaluations and comprehensive presentations of advanced knowledge in every area of the discipline.

304 pages April 1976 $29.10/£16.75

MICROBIAL PRODUCTION OF NUCLEIC ACID-RELATED COMPOUNDS

edited by **K. Ogata,** *Kyoto University;* **S. Kinoshita,** *Kyowa Hakko Kogyo Co. Ltd;* **T. Tsunoda,** *Ajinomoto Co. Inc.,* and **K. Aida,** *Institute of Applied Microbiology, University of Tokyo.*

This book includes details of various newly established techniques for the industrial production of nucleotides, and of studies on the production of nucleic acid-related compounds.

366 pages November 1976 $30.00/£18.25

Published by Kodansha Ltd., and distributed by John Wiley & Sons Ltd.

A New Quarterly Journal:

INTERNATIONAL JOURNAL OF ENERGY RESEARCH

The area of Energy research and development is faced with several obstacles. It is an important and rapidly expanding but broadly interdisciplinary field at a time of severe financial restraint. Its rapid expansion has meant a fragmentation of the literature and severe communication difficulties between workers. Frequently work of high utility and calibre receives less attention than its due partly because it does not reach a wide enough audience, either through the specific circulation of the journals used, or because there exists no suitable vehicle – particularly in the case of scientific and technological research. The **International Journal of Energy Research** aims to satisfy this need and provide an interdisciplinary platform for the results of energy research without the constraints imposed by aiming at a restricted audience. The subject matter of the journal will be concerned with the development and exploitation of both traditional and new fuels and other sources of energy, and an interdisciplinary approach to this interdisciplinary subject will be encouraged.

Problems of memory representation

Processes of Animal Memory. Edited by D. L. Medin, W. A. Roberts and R. T. Davies. Pp. xi+267. (Hillsdale, Lawrence Erlbaum Associates: New Jersey, 1976. Distributed by the Halsted Press Division of Wiley: New York and London, October 1976.) $19.00; £11.50.

THIS book is useful because it collates a set of papers by authors who have all worked closely together in the past on problems of memory representation. It demonstrates that the problems of inference of the existence and nature of mental representations in animals are, indeed, formidable, but that with ingenuity much can be said about such possibilities, and that perhaps we can no longer talk sensibly about learning theory if we omit them. It also shows that the questions raised when proper investigations are made are far more interesting than those with which psychologists have fobbed off laymen and bored each other for so long.

The first paper by Ruggiero and Flagg directly takes up these issues. It reviews neglected early work, and describes interesting new work by Medin and Davis, among others, which shows that monkeys find some patterns easier to learn than others. This fact seems trite until the data are considered in terms of the regularities of patterns which are particularly striking to animals. It is not simply that such regularities may reflect the organisation of perceptual analyser systems as postulated by Sutherland, Mackintosh, *et al.* The regularities may also usefully be described in terms of the principles of encoding economy which have been so useful in extending the application of information theory to human pattern recognition. We may talk, though still loosely, of an animal making "the best sense" of a pattern, by selectively remembering its critical rather than incidental characteristics.

The application of paradigms and models conventional in the study of human short-term memory to animal work is a major theme of this symposium. A paper by Davis and Fitts shows that the modifications of paradigms required is not as great as had previously been thought. Although the empirical data they present are as yet too scanty for theoretical treatment, they have already shown that provocative similarities and differences in obtained data do not demand separate theoretical constructs for humans and monkeys.

A charming paper by Bolles revives the study of 'insight' in animal learning which has always been a standing challenge to behaviourists, and which is the current preoccupation of modern systematic theorists such as Levine. There is, perhaps, too much emphasis on the "Garcia effect", or "stomach memory", that is, the tendency of even lower mammals, such as rats, to avoid specific foods when they have been poisoned (non-fatally!) up to an hour after eating them. Demonstrations that rats will avoid eating in one place rather than another under similar circumstances are interesting. But a further demonstration by Riley that animals poisoned after drinking water show subsequent aversion to novel solutions such as saccharine (control data are not quoted) are less interesting than the author supposes. Rats always tend to avoid novel foodstuffs, and show a cautious empirical approach, eating very little until no uncomfortable consequences have ensued on several occasions. Although rat-catchers may feel their darkest suspicions of rodent cunning have been confirmed, it is still too early to take these as demonstrations of the understanding of 'causal relationships' by lower animals, as Bolles would wish us to do. He is nevertheless quite right to point out that it is time to seriously consider whether the rigid tenets of stimulus–response learning do not require further testing in this regard. The perception of "rules" and "regularities", and the perception of "causality" shade into each other in ways uncomfortable for older theorists.

A concluding paper by Whitlow attempts a direct reinterpretation of the most elementary S-R learning theory, classical conditioning theory, in terms of temporal organisations of events ("episodic memory theory") now current in the literature on human memory. The conceptual failures involved are illuminating. Perhaps as much for the human as for the animal work. **Patrick Rabbitt**

Whither goest palaeoecology?

Structure and Classification of Paleocommunities. Edited by R. W. Scott and R. R. West. (Wiley: New York and London, 1976.) £18; $30.

THIS child is the offspring of 15 authors and was born two years after an American Paleontological Society Symposium held at Miami Beach in 1974. The creative impulse was triggered by the question "Whither goest palaeoecology?". The book consists of 11 chapters of which the first four are basically reviews of community concepts in palaeoecology (Kauffman and Scott), two chapters on classification in terms of trophic levels (Scott) or environments (Parker), and a comparison of living and dead assemblages (Macdonald). The remaining seven chapters are more specific studies related only by having a palaeoecological bias. They range from living communities of the S. Californian shelf (Stanton), through Mexican and Californian living and recently dead molluscs and foraminifera (Warme, A. A. Ekdale, S. F. Ekdale and C. H. Peterson), Pleistocene ostracodes from Utah (Lister), Eocene nonmarine molluscs from Wyoming and Colorado (Hanley), seven lingulid communities of different ages (West), Pennsylvanian ostracodes from Kansas (Brondos and Kaesler), to Mississippian communities from Georgia (Broadhead).

Understandably definitions of communities differ. "A paleocommunity is the suite of preservable taxa comprising a community (pvi)"; as for communities they can be regarded as "a unique congregation of diverse organisms having a unique structure based on organism interactions . . ." (p18); "recurrent groups of numerically co-occurring species" (p143); and (p88) "a group of species which are often found living together".

Most of the authors avoided answering the original question of where the subject was going and preferred to explain where they and others had been. And since vertebrates, plants, trace fossils and substantial parts of the invertebrate palaeoecological record were, in effect, not touched on (and in fairness to the authors nor could they have been within the compass of a slim volume) it is not surprising that the product is a ragged patchwork of individual interests. The frequently overlapping references and interests are predominantly American. A *much* more interesting project would have been to pose the same question, quite separately, to another group of 15 palaeoecologists in the States, and comparable groups in say, Canada, Britain, France, Germany and Russia, and then compare the products.

The blurb claims that the book serves as a fascinating historical overview of the significant advances in community ecology and palaeoecology from the 1950s to the present day, and is an unprecedented summary of current knowledge. The publishers have prudently set the price at £18.00. **G. Y. Craig**

G. Y. Craig is Professor of Geology at the University of Edinburgh, UK.

Anti-bacterial therapy

The Battle Against Bacteria: A Fresh Look. By P. Baldry. Pp. 179. (Cambridge University: Cambridge, London, New York and Melbourne, 1976). £4.50.

ONLY six of the 15 groups of anti-bacterial drugs now in wide use were available 20 years ago. Since then, however, the spectre of transferable drug resistance has become the constant adversary of microbiologist and clinician alike. These dramatic changes are emphasised by even a superficial comparison of the two editions of Dr Peter Baldry's history of anti-bacterial therapy. The first edition, although published in 1965, took the story only up to the late 1950s and occupied a compact 100 pages. Inevitably its successor is over 70% longer. It describes the evolution of a field which is a fascinating meeting ground of microbiology, clinical medicine, biochemistry, pharmacology and molecular biology.

The book is least successful when summarising the history of bacteriology as distinct from therapy. Thus Leeuwenhoek did not see the 'animalcules' which cause disease; he saw only saprophytes and normal commensals. His illustrious predecessor Robert Hooke is not mentioned, even though an engraving from Hooke's *Micrographia* is included (without attribution). Joseph Lister's pioneering bacteriological work—which included isolating the first pure bacterial cultures —also goes unnoticed, as does his even more relevant observation of 1871 on the antibiotic action of *Penicillium* cultures. Moreover, Lister was not Professor of Surgery at Edinburgh but in Glasgow at the time of his original discovery of antisepsis. The romantic legend of the martyrdom of Semmelweiss also needs correction. This tragic pioneer of hand disinfection in obstetrics in fact suffered from chronic paranoia. After increasing insanity necessitated his commital to a mental hospital his death from presumed streptococcal septicaemia—following a hand injury—was supreme irony. For this was the infection he had prevented in thousands of women during childbirth.

The author is on much firmer ground with his main theme—the discoveries of anti-bacterial drugs. There are only two major disappointments here—apart from the lack of any references: the story of the British work on sulphonamides (culminating in M&B 693) is omitted, and the central chapter on Fleming's original observations of 1928 remains unchanged from the first edition. There is no mention of the fascinating revelations published in 1970 by Fleming's colleague, Ronald Hare. In his book *The Birth of Penicillin*, Hare showed that almost every detail of the familiar story is erroneous. Nevertheless, Dr Baldry's book is a good introduction to an enthralling subject. It should attract a wide audience.

Noradrenaline and adrenergic nerves

Peripheral Sympathetic Neurotransmission. By W. De. Potter. Pp. xv+161. (Arscia Uitgaven, NV: Brussels, 1976.)

THIS book is a strongly personal account of the longstanding research interests of the author and his laboratory. Since he is an acknowledged leader in his field, it is predictably a good account of the biochemical aspects of the synthesis, storage and release of noradrenaline from adrenergic nerves. Factors affecting the storage and release, such as electrical stimulation, and α- and β-receptor-blocking agents, are also described. The relationship between the different noradrenaline-containing particles is discussed. There is a clear and informative diagram at the end of the book which summarises the author's views of the origin and fate of noradrenaline storage particles. The sections on methods are especially good and should be most useful to those engaged in this area of research. The bibliography is fairly extensive (270 references) although it stops at 1973.

My one reservation is related to the title. In my opinion, this title implies a general coverage of all aspects of transmission including information on neuroeffector geometry, the electrophysiology of transmission, and effector cells including 'receptor' characteristics. These topics are not discussed. There is also little account of transmitter inactivation mechanisms. I have, however, no hesitation in recommending this book for its lucid description of storage and release of noradrenaline from sympathetic nerves. It would make a useful addition to the library of anyone working in the field of neurotransmission. **G. Burnstock**

G. Burnstock is Head of the Department of Anatomy and Embryology at University College, London, UK.

Electric fields and isolated atoms

Atoms and Molecules in Electric Fields. By N. Ryde. Pp. 455. (Almqvist and Wiksell International: Stockholm, 1976.)

THE effect of external electric fields on the spectra of isolated atoms and simple molecules has been investigated since early this century. In particular the splitting and shifts in spectral lines observed as the external field is increased, resulting from the perturbation of otherwise spatially degenerate levels, have been important in the development of quantum theory. These 'Stark effect' measurements continue to provide important information on oscillator strengths and the assignment of spectra. Increasingly though, interest has shifted to the application of these effects, for example, in astrophysics or plasma studies where the broadening or line shift can be related to the electron density and temperature. There is thus a need, identified by the author, for a critical compilation of the large amount of data amassed in the past forty years for use in these new areas.

The most substantial and useful section of this book forming about 50% of the whole is just such a compilation of the experimental or calculated electric field properties of some fifty atoms and atomic ions, much of this work dating from the 1920–1930s. Spectral assignments are discussed and plots of line displacement with field strength are recorded here. A large part of the remainder of the book is concerned with the quantum theory of these processes. This section begins with a detailed account of elementary perturbation theory and then reviews the application and development of these techniques in a wide range of atomic and molecular situations.

The other chapters in the book dealing with experimental matters and molecular species are rather limited in scope and will be of only limited interest to the type of reader for whom this book is intended. The use of the phrase 'canal ways' throughout the book makes a curious impression. There is no index.

This book will be a useful reference for those using the atomic 'Stark effect'. **Malcolm Fluendy**

Malcolm Fluendy is Lecturer in the Department of Chemistry, University of Edinburgh, UK.

Human rights and the scientist

'SCHOLARS of all kinds continue to be oppressed and persecuted in many parts of our contemporary world, and concerted attempts to impede their enquiries and suppress their conclusions are as common today as at any time in the past'. So begins a newly published report *Scholarly Freedom and Human Rights* (Barry Rose Publishers Ltd, £2.25) by a study group of the Council for Science and Society in collaboration with the British Institute for Human Rights. No documentation is given for the statement; indeed, the group has deliberately avoided quoting examples, but anyone with a mite of political awareness will know exactly what they are talking about and also that oppression is not restricted to any particular part of the world.

The central theses of the report are two: that there is a substantial body of international human rights law which should be adequate to cope with the sort of violations that are depressingly familiar; and that scientists, depending so much on communication, are peculiarly prone to what may seem to others to be minor constraints or irritations. Isolate an accountant from the literature and from his colleagues for a few years and afterwards he could soon pick up the threads of his profession; do the same to a scientist and his whole career may be ruined and others' impoverished.

The human rights legislation that has accumulated since the 1948 United Nations Universal Declaration of Human Rights is extensive, and the report provides a valuable guide. Of central interest to scientists are assertions such as that of the United Nations Declaration: 'Everyone has the right to freedom of opinion and expression; this right includes freedom to hold opinions without interference, and to seek, receive and impart information and ideas through any media and regardless of frontiers.' The problems, however, arise in the qualifications. The United Nations Declaration is only proclaimed as a 'common standard of achievement'—highly desirable but not legally binding. A document which binds its members and which provides a mechanism for redress—the European Convention on Human Rights—says almost the same thing, but it then goes on to add 'the exercise of these freedoms . . . may be subject to [legal and democratic] restrictions . . . in the interests of national security, territorial integrity or public safety, for the prevention of disorder or crime, for the protection of the reputation or rights of others, for preventing the disclosure of information received in confidence, or for maintaining the authority and impartiality of the judiciary'.

Some of these restrictions, the report points out, do no more than prevent anyone who does things like shout 'Fire!' in a crowded theatre from avoiding the legal consequences by claiming freedom of expression. But there are plenty of murky areas connected with 'national security', 'protection of morals' and so on, and it is a disappointment that the study group, having noted these areas, did not pause at such a point and devote rather more than three paragraphs to a discussion of the subject. Also, having drawn attention to differences in priorities between countries operating different economic systems, the group could well have elaborated rather more on the problems of misunderstanding between countries which rate civil rights high but give less guarantee of economic benefits and those which have an opposite order of priorities. There is one paragraph in the report in which it suddenly seems possible that this question will be analysed in depth, but the opportunity is passed over.

But what should scientists do when they hear of violations of human rights? We have not just an internationally accepted right to protest, says the report, but a duty to do so, and in a public way both individually and through organisations such as learned societies. Private persuasion is allowed its place but the major sanction 'must always be that of public protest'. The clear intention of the report thus emerges in its last few pages—bodies such as the Royal Society have no business steering clear of public pronouncements on the oppression of scientists.

Not for the first time, however, the Council for Science and Society has almost predetermined the conclusions of a study group by its choice of membership of that group. We greatly admire the vigour of John Ziman, convener of the group, and the integrity of its members—though it hardly seemed necessary for them to write that they all 'share a high degree of commitment to the ideal of the relentless and objective search for knowledge, wherever it may lead'. But was the outcome ever in doubt? Professor Ziman's views are well known on the subject of Royal Society intervention, and this makes the report's conclusions seem less weighty than they would have been had the Council gone to someone less committed to convene the group. The excellence of the sections on human rights law and on the needs of scientists remains undiminished. They should be widely read, and the hope must be that the document will have some effect. But its conclusions, put together a little skimpily as if they were self-evident, lack the coresponding weight. □

Peace research: the whys and the wherefores

Frank Barnaby, head of the Stockholm International Peace Research Institute (SIPRI), outlines the course being followed by military technology and offers his view on the role of peace research

"WITH the continuing technical progress and the current world-political constellation, it is highly probable that there will be an atomic world war before the end of this century." This statement was recently made by Professor Carl Friedrich von Weizsäcker, the West German physicist-philosopher, Director of the Max-Planck Institute in Munich, and author of the widely-discussed book *The Relevance of Science*. According to Professor von Weizsäcker a nuclear world war will probably be followed by the establishment of a world government which will ensure that no more nuclear world wars occur. In his view, then, it is likely to be the Third World War which will end all world wars.

Most students of military technology would agree that the probability of a general nuclear war is increasing—at least if only the consequences of advances in and the spread of military technology are taken into account. Three specific factors contribute to this conclusion. First, the nuclear arms race between the USA and the USSR could (and, therefore, probably will) eventually lead to a first-strike capability. This does not necessarily mean that one side will be able to destroy completely the other's capability to inflict casualties and damage in retaliation for a first-strike, but rather that this capability may be perceived to be sufficiently reduced to limit the casualties and damage to a level that might be considered acceptable for a given political goal. This level will depend on the recklessness and adventurousness of the political and military leaders in power at the time.

First-strike strategic nuclear weapons are likely to result from the improvement in accuracy of ballistic missiles. The accuracy of the current US Minuteman III land-based intercontinental ballistic missile, for example, is about 400 metres, at a range of about 13,000 kilometres. By the mid-1980s warheads with accuracies of about 30 metres may be available which, by any standards, will be first-strike weapons, even against small hardened targets. When it is remembered that the German V-2 missile could barely be depended on to hit London, the rate of progress which has been and which is still being made in missile technology will be realised. And similar progress has, of course, been made in many other areas of military technology.

If the limit has nearly been reached in the performance of strategic offensive missiles, there is still some way to go in strategic defensive systems. Much research is under way in defensive weapons against ballistic missiles and in anti-submarine warfare. A breakthrough in these areas, which can by no means be discounted, would be extremely dangerous for world security.

When the political and military leaders perceive a first-strike capability to be near they may intensify measures to defend the population, and to protect industry and vital plants from nuclear explosions. The effectiveness of these measures will of course be taken into account when assessing first-strike capabilities. That perceptions about "winning" a strategic nuclear war are likely to be proved wrong, if ever put to the test, is hardly a consolation, since civilisation as we know it will be destroyed in the process.

The second reason for concern is the worldwide spread of the capability to produce nuclear weapons, through the spread of peaceful nuclear technology, and of the technical knowledge and expertise required for nuclear-weapon production. It is extremely unlikely that any new international measures to establish a viable non-proliferation regime will succeed where the Non-Proliferation Treaty has failed. The most that can be hoped for is that measures—such as moratoria on the reprocessing of reactor fuel elements to remove the plutonium from them and on the large-scale construction of breeder reactors—will be taken to slow down the rate of proliferation.

The Achilles heel of the proliferation problem is that sufficient fissile material for a modest nuclear force could be obtained, by virtually any country wishing to do so, on a small scale, and secretly. The components for a small reactor able to produce enough plutonium for say two atomic bombs per year are available on the open market. And the reprocessing of a few tens of kilograms of plutonium annually could be done on a laboratory scale. The indigenous clandestine construction of a small uranium enrichment plant is also within the capabilities of many countries.

It is already hard to know for certain whether or not some countries have, or are producing, nuclear weapons (Israel, for example, has kept the world guessing for years), and this uncertainty will increase with time.

The third factor is the international trade in arms which is spreading the most sophisticated conventional arms worldwide. Since the October 1973 Middle East war this trade has increased at an unprecedented rate and is now virtually out of control. As a consequence, the arsenals of some Third World countries are more up-to-date than are those of some industrialised countries. Many of the aircraft and missiles supplied to the Third World are capable of delivering nuclear weapons (on today's standards, even a crude nuclear weapon with an explosive power equivalent to that of 20,000 tons of TNT should weigh less than 1,000 kg).

Some of the major recipients of arms become strongly bound to the supplier state, often to an extent hardly distinguishable from that of a close ally. This dependence is considerably heightened by the knowledge that in modern war munitions — particularly anti-tank and anti-aircraft missiles—are normally used at a very high rate. Victory may depend on the willingness of a great power to provide the massive quantities of replacements needed throughout the war. In this sense, the great power often becomes, implicitly or explicitly, the guarantor of the client state.

A war in, for example, an unstable region, involving one or more of these client states, could escalate from a conventional war to a limited nuclear war fought with the nuclear weapons of the local powers and then to the involvement of the great powers, committed to defend their clients—an involvement which might end in a general nuclear war. This end result is, of course, most likely to occur if one of the great powers perceives the chance of making a successful first-strike.

While not disputing the dangers inherent in unrestrained military technology, there are those who argue that increasing cooperation between states —in, for example, economic affairs—will prevent the great powers from pursuing policies which lead to a general nuclear war. Whether or not tendencies for cooperation will, in the next two or three decades, outweigh those for confrontation is a matter of personal judgment. I find it hard to be optimistic given the rapid rate at which military technology advances and the relatively slow rate at which effective bonds between nation states are formed.

Taken together, the three factors

will produce an extremely dangerous period in the not too distant future, unless steps are taken to prevent it. If, for example, a first-strike capability is developed it will take a very strong-willed and responsible leadership to resist arguments for its use. With so much at stake for us all, can we really afford to sit back and hope that the right men will be in power at the crucial times?

There is no reason why the current rate of progress in military research and development, the activity mainly responsible for progress in military technology, should not be sustained. In fact, because R&D is the most difficult of all military activities to control, one can expect the rate of progress to continue to increase. Military technology has indeed come a very long way since the Second World War. Where will this technology take us by the end of this century? Scientists who ponder this question are generally doomsayers.

All of the ramifications of advances in military technology are known only to an extremely small group of people outside governments—to a few hundred scientists worldwide. It is a sobering thought that even within the world's governments at most a small handful of political leaders and their advisers are aware of the consequences of the onward rush of military technology. Under these circumstances and given the catastrophic nature of nuclear war, are the few scientists who do know the facts under a special obligation to publicise them?

The social responsibility of scientists has been much discussed over the past twenty years but inconclusively. There does, though, seem to be wide agreement that scientists do at least have a duty to inform non-specialists about any scientific developments (or the application of research results) which could lead to adverse social consequences. And the more dire the consequences then presumably the greater the duty to inform. But to whom should the information be addressed? In what form should it be presented? And how can its dissemination be best achieved?

These questions are particularly relevant to the Stockholm International Peace Research Institute (SIPRI), an independent institute established in 1966 and financed by the Swedish Parliament, which publishes factual studies on military technology, armaments, and disarmament (see *Nature*, **246**, 397–400; 1973). During SIPRI's lifetime the situation in armaments and disarmament has changed considerably. Ten years ago there was still reason to hope that arms control negotiations would succeed in stopping the Soviet-American arms race and lead, step-by-step, to significant disarmament. We now know differently. Throughout this period, the arms race has continued virtually unconstrained and the only weapons destroyed by international agreement have been biological weapons — weapons of little military interest.

Arms control may lead to the management of the arms race. Arms control may contribute to Soviet–American détente. But, other than the actual negotiators and committed political leaders who soon develop a high level of 'professional optimism', few now believe that the arms control approach will actually lead to disarmament.

> 'There is no reason why the current rate of progress in military research and development, the activity mainly responsible for progress in military technology, should not be sustained. In fact, because R & D is the most difficult of all military activities to control, one can expect the rate of progress to continue to increase'

In my opinion, this lack of success, and the resultant ever-increasing probability of nuclear war, demands urgent action. Whereas in the mid-1960s it seemed that SIPRI's research should be aimed at the specialists advising those decision-makers and diplomats able to affect arms control negotiations, it is now clear that a much wider audience must be reached.

The political leaders of the great powers clearly lack the will to negotiate nuclear disarmament. There are two possible ways of applying the necessary pressure on these reluctant politicians. One is through public opinion, or at least the most influential sections of it, and the other is concerted action by the smaller countries.

SIPRI has neither the skills nor the resources needed to appeal directly to the public. But it can, and does, provide information in a form easily used by those who have — particularly journalists working for the press, radio and TV. SIPRI also makes sure that its material reaches the relevant authorities in the smaller powers.

A few of these powers—Canada, Mexico, the Netherlands, Sweden and Yugoslavia, among others—have a sizeable group of officials well trained in disarmament and related matters. But the bulk of the smaller countries do not. The one or two individuals in these countries dealing with the subject need information in a summarised and easily digested form which should also give a sense of the urgency of the current situation. An authoritative institute is able, and most would say has the duty, to provide this crucial service in addition to its various research publications.

All of this pre-supposes that far-reaching disarmament (beginning with nuclear disarmament) can be directly negotiated in today's world of 150 or so states using the traditional methods of diplomacy and international law. SIPRI believes this to be so. SIPRI also believes that unless this process is soon begun it may be too late to prevent a nuclear world war.

Some peace researchers, however, reject these beliefs. They argue instead that conflict—leading eventually to general nuclear war—is inevitable because of the very nature of the present international system. The only way to prevent this, they say, is to change totally the system by developing entirely new international political and social institutions. In their view it is unrealistic to expect today's world to disarm, and even if it did the likelihood of nuclear war would remain. In my opinion, this approach is not only incorrect but dangerous. There is probably insufficient time to produce a new world order, even if such a thing were feasible. And there is the danger that too much emphasis on the inevitability of nuclear war may make it a self-fulfilling prophecy.

In summary, I believe that the dissemination of objective information on armaments and disarmament to specialists is still crucial but it is not enough. In addition, it is necessary to explain to non-specialists where military technology is taking us—particularly to the groups mentioned above—in a way which will stimulate their interest and hopefully provoke them to action. In this sense, SIPRI's work has become somewhat more 'political'.

The fear that the presentation of material in a brief and readable (even somewhat enlivened) form must damage the reputation for objectivity of a research institute is, in my opinion, unfounded. When the need for political effectivity is urgent and great it is even defeatist. ☐

Czechoslovakia (1)

The general . . .

A Special Correspondent discusses the climate in which science operates in Czechoslovakia

THE fact that by comparison with Czechoslovakia probably no other state in the world has so many members of its political leadership with the highest academic qualifications seems to express a very attractive idea—namely, that educational opportunity is equal for everyone, that political leadership emerges in a democratic way and that people make rational choices for the best of the society. The logical conclusion that those who take decisions are the most competent is undermined by two factors.

First, in practice it is the Communist Party which is the repository of power. For example, only those scientists who conform to party rulings are acknowledged as scientists. And the acquisition of school qualifications or of a university degree and high academic honours in the space of months may well accompany a person's improving political fortunes. Still, the fact that political leaders regard it as worthwhile to present themselves as academics symbolises the significance which they attribute to the community of learning.

Secondly, some prominent intellectuals in Czechoslovakia are now in revolt against the present regime. The *Charter 77* human rights manifesto, originally signed by more than 200 persons of "various shades of opinions, faiths, and professions", included some 25 scientists and doctors. It has since been countersigned by at least another 200 supporters, and contains a number of accusations of relevance to all who value academic and scientific freedom (see box).

The current Five Year Plan (1976–80) shows clearly that the present leadership continues to hope for an important contribution of science to economic development. Expenditure for research and development is to grow by a third of the present sum to 3.8% of GNP in 1980, and the proportion of people working in science and technology is to be 21 out of every thousand working in general. Expenditure on equipment has nearly doubled in the past five years and is to grow still further; so will the salaries of scientists.

The significance attributed to science by the present regime in Czechoslovakia is not just theoretical. Yet the apparently grave difficulties achieving the expected results from the effort put into science seem more and more clearly to arise from the problems inherent to the system itself and not just from the capacities of its leadership.

Of the two different views about the preconditions for the advancement of learning—one stressing free inquiry, the importance of competition and the natural selection of ideas, the other maintaining that an attainment of shared norms and procedures by the scientific community is desirable and that scientific effort as a whole can and should be rationalised—communist ideology is decisively in favour of the second view, since it believes that the development of science can be encouraged when planned. Virtually the whole of scientific effort is subject to state planning in Czechoslovakia.

Even though science is administratively subordinate to the central agencies of government, it would be misleading to say that one identifiable centre prescribes what should be done. Short-term plans spell out work assignments for practically every scientist; this is done on the basis of two-yearly surveys of the country's material and manpower resources in science. The latest of the regular five-year plans was worked out by 800 scientists and specialists from production, directors and representatives of the relevant working places and, of course, government ministries. Political supervision comes only through the political bounds on the participants themselves. Occasionally mention is made of preparations for a long-term plan, but so far nothing has materialised.

One of the basic difficulties is the right balance betwen research and development assignments. The current five year plan for Czechoslovak science foresees 346 main tasks; 70% of these are oriented towards current technical developments, 23% are concerned with other social needs, such as medicine and social science, and 7% are tasks of pure research. The proportion of uncommitted to committed goals is, even in the country itself, considered low.

One problem frequently pointed out in Czechoslovakia is the highly unnatural age-structure of people working in research. The official figure for the average age is 45, but this does not express the fact that there is a whole generation missing. After the continual purges in the early 1970s and the emigration of many highly qualified scientists to the West, the number of people between 30 and 50 diminished drastically. There are institutes where only isolated persons survived the past few years. The zigzag course of Prague's present policy has meant alternating periods of relative reconciliation and dogmatic reassertion. Changes and deviations from the science plan require a very expansive, unproductive bureaucracy, and the administrative complex is very demanding of scientists' time—especially when taken together with permanent political courses and meetings.

'A virtual apartheid'

Some extracts from the *Charter 77* human rights manifesto:

•

The right to freedom of expression . . . is in our case purely illusory. Tens of thousands of our citizens are prevented from working in their own fields for the sole reason that they hold views differing from official ones, and are discriminated against and harassed in all kinds of ways by the authorities and public organisations. Deprived as they are of any means to defend themselves, they become victims of a virtual apartheid.

. . . . countless young people are prevented from studying because of their own views or even their parents'. Innumerable citizens live in fear of their children's right to education being withdrawn, if they should even speak up in accordance with their convictions.

Any exercise of the right to 'seek, receive and impart information and ideas of all kinds, regardless of frontiers, either orally, in writing, or in print' . . . is followed by extra-judicial and even judicial sanctions . . . •

No philosophical, political, or scientific view or artistic activity that departs ever so slightly from the narrow bounds of official ideology or aesthetics is allowed to be published.

Many scholars, writers, artists and others are penalised for having legally published, years ago, opinions which are condemned by those who hold political power today.

All national institutions and organisations are in effect subject to political directives from the machinery of the ruling party.

Clause 2, article 12 of the [International] covenant [on Civil and Political Rights] guaranteeing every citizen the right to leave the country is consistently violated or under the pretence of 'defence of national security' is subjected to various unjustifiable conditions . . . The granting of entry visas to foreigners is also treated arbitrarily, and many are unable to visit Czechloslovakia merely because of professional or personal contacts with those of our citizens who are subject to discrimination.

Czechoslavakia (2)

. . . and the particular

Vera Rich considers the position of scientists in the Slovak Republic

SOME Western analyses of the Soviet and East European interest in detente stress their need for modern technology. Insufficient modernisation of industrial production in these countries is said to be due to the difficulties in implementing new technologies. The problem may not be a simple mechanical one, though; it may also be related to the relegation of science to the status of a mere tool whose direction has been predetermined by the needs of society.

One of the main tenets of science policy throughout the Comecon block is the tightening of links between research and industry. The place of science in the economy is assessed primarily for its practical and immediate benefits. In the case of a relatively newly-developed area such as Slovakia, which for many years was the 'backward' partner of the Czechoslovak federal state, this can mean that scientists bear responsibility for deficits due largely to planning errors and past neglect.

Slovak research scientists have recently been blamed for deficiencies in the local metallurgical and engineering industries. This involves some 40% of all research workers in Slovakia, or more than 15,000 persons. According to the November 1976 meeting of the Central Committee of the Communist Party of Slovakia, "the slow introduction of new ideas in production and the contribution of research institutes so far are not satisfactory." There is a high turnover of leading technical and managerial personnel, weaknesses in planning and leadership, and a general failure to use modern equipment to the best of its ability.

Federal planning aims to "balance the sociopolitical and economic standards of the Czech and Slovak republics" and the development of Slovak industry is a major theoretical issue. The need for such a development is reflected in the targets for the present Five Year Plan: overall Czech industrial production is to be increased by 32.3% and Slovak production by over 44%. This means that output from Czech industrial enterprises must rise by 48.5% and from Slovak enterprises by 70%. The targets are a 50% rise in Slovak exports with engineering exports in particular rising by 100%. It is difficult to imagine that all these figures will be met, particularly as Slovakia's main 'export' products—steel and aluminium—are not in fact exported in ingot form, but go to Bohemia to be manufactured into finished articles, which are then credited to the Czech Republic.

The slow growth of Slovak industry is partly historical in origin—when the Czechoslovak Republic was set up by the Treaty of Versailles, the Czech lands, which had been under Austrian rule, already had flourishing industries, while Slovakia, which had formed part of the kingdom of Hungary, was largely agricultural. The policy of the First Republic was to maintain this *status quo* thereby causing considerable Slovak resentment against the federal government. During the late 1940s the industrialisation of Slovakia was a major issue. Students uncertain of which subject to pursue were urged into technology, in particular metallurgy.

One of the first actions of the new communist government was to start planning the vast East Slovak Iron Works at Košice. This was primarily a political decision: the only resources the area could offer were limestone for fluxing and a large labour force. Iron ore had to be brought from the Ukraine and coke from Czech Silesia. One of the charges bought against Slansky, the former Party Secretary, during his trial in 1952 was that this was an "impossible" scheme, and construction at the plant was halted for three years. In 1968, when open discussion became possible under the Dubček regime, it was revealed that steel produced at Košice was costing 8–10 times that produced in Japan, although Japan was shipping iron ore from Australia and Brazil and coke from Australia. Since 1968, the Husak government has invested sums in Slovak industry which are out of all proportion in comparison with the population of the republic, causing some resentment from the Czechs. The Slovaks, however, stress the need for even more investment. In September, 1975, Miloslav Hruskovic, the Secretary of the Central Committee of the Slovak Communist Party, noted that "serious problems persist in the capital investment plan", and that scientific and clinical development has not been "reflected in investment construction as much as it should have been" (no details were given).

Camera Press

Gustav Husak, Communist party head

Improvements

Certainly investment has produced considerable improvements. During the 1971–75 period industrial production in West Slovakia (mainly chemical and engineering) is said to have risen by 54.6%, while in East Slovakia the "volume" of production increased by 66.2%. There was considerable investment in the chemical works at Bratislava, and the notorious Košice ironworks now has the second highest output of all Czechoslovak metallurgical plants, and the lowest manufacturing costs (no details given). And although the Federal reports indicate a general lack of enthusiasm and expertise in the use of computers, particularly for information and planning work, the development of a scientific and technical information system in Slovakia was, according to the Slovak Minister of Development and Technology, J. J. Busa, going forward well. The new arrangement, by which Cuba will supply the Comecon countries with nickel will undoubtedly benefit the nickel-works at Sered, which until now has had to use ore from Albania.

Nevertheless, according to Hruskovič, what is needed is a greater intensification of production, together with a more economic use of raw materials, commodities and energy and an improvement in quality and technical standards. The Central Committee of the Slovak Communist Party proposes a stick-and-carrot policy for scientists and technologists: those who "have the courage to take risks on the challenging part of technological progress" will receive "moral rewards" and sharply-differentiated "material incentives" unhampered by "unwarranted egalitarianism, because this slows down progress". Those, however, who cannot "cope with the tasks of the present", should be transferred to other posts "tactfully, and before it is too late". ☐

BRAZIL

A growing resistance

Bruce Handler reports from Rio de Janeiro on recent developments involving the controversial German–Brazilian nuclear deal

Attempts by the Carter Administration in the United States to undermine the controversial nuclear technology agreement between West Germany and Brazil are resulting in precisely the opposite of what Washington wants. Brazil are resulting in precisely the go through with the atomic pact. Formerly divergent internal currents in Brazil are rallying behind the Brazilian government in defence of the agreement with Germany And other Latin American countries—especially Argentina, which has always been considered Brazil's principal rival—are sticking up for Brazil in an unusual display of Latin American solidarity.

Part of Jimmy Carter's election campaign platform consisted of promises to oppose the spread of nuclear technology, especially in the underdeveloped Third World. And just a few days after taking office, he dispatched his Vice President, Walter Mondale, to West Germany to ask Chancellor Helmut Schmidt to reconsider German plans, under the nuclear agreement, to aid Brazil in developing its own full-fuel cycle. This German knowhow is to allow Brazil to enrich its own uranium for use in electricity-producing nuclear reactors, but it also will make Brazil theoretically capable of producing plutonium—a key ingredient in nuclear weapons

After some initial backtracking, however, Germany said it will go ahead with the Brazilian agreement as planned. Brazil declared flatly that it "sees no possibility" of altering or delaying the pact, as the United States wants. And Paulo Nogueira Batista, the head of the Brazilian government's nuclear power company, Nuclebras, told the press: "The agreement is being carried out on schedule, and in some cases you could say we are making even more progress than we expected."

Brazil's foreign minister, Antonio F. Azeredo da Silveira, did say later, though, that Brazil is willing to discuss "global aspects" of the problem of the spread of nuclear technology This, the minister noted, ought to prove to President Carter that Brazil intends to act like a responsible, adult nation Azeredo da Silveira invited the US Secretary of State, Cyrus Vance, to Brazil for talks, and it appears Vance will come.

The attempted pressure-play from Washington resulted in a remarkable outpouring of unified internal support for Brazil's authoritarian, military-run government, which had pressed hard to get the nuclear agreement with Germany in the first place The actual agreement was signed in mid-1975, but the Brazilians had begun secretive negotiations with the Germans several years earlier.

Marcos Freire, a senator from the sole opposition political party permitted in Brazil, said "The United States has no moral authority to interfere with the nuclear treaty." He speculated that "powerful economic interests" might be behind Washington's meddling, in view of the fact that the total value of contracts to be signed under the Brazilian–German agreement is conservatively estimated at $5,000 million

Another member of the opposition party, Representative Joao Cunha, said Brazilian President Ernesto Geisel, "speaking in the name of all Brazil's 110 million citizens, should repudiate this US manoeuvre."

Even Brazil's academic and scientific community, which under the current government tends to stay as far away from politics as possible, has spoken up with regard to the nuclear agreement. "This government is correct in not permitting outside interference in affairs over which it has exclusive sovereignty," said Professor Marcelo Dami, a physicist from Sao Paulo. Dami made it clear that he did not like the secretive way in which the government had gone about negotiating the agreement with the Germans and also that he has reservations about the type of fuel that was chosen for atomic reactors that are to be built in Brazil under the pact. "But disagreements of this nature now must be put in the background, in view of higher national interests that are at stake," he said.

Helio Jaguaribe, a political scientist whom some members of Brazil's military regime regard as a "dangerous intellectual," also came out in full support of the government. "President Geisel deserves the warmest applause from all Brazilians for the firm position he has taken in supporting the agreement," he declared "President Carter's concern about the proliferation of nuclear weapons is fully valid But Brazil has no nuclear weapons, and it does not intend to have them."

He said a distinction has to be made between stopping the proliferation of nuclear weapons and "the desire of the superpowers to maintain a monopoly on nuclear technology" The Brazilian government, furthermore, was "absolutely right in not signing the Nuclear Non-Proliferation Treaty," since to do so "would perpetuate the underdevelopment of third world countries."

Unexpected defence for Brazil came from across the border in Argentina, which until now has been wary, to say the least, of its fast-developing neighbour's nuclear energy programmes and goals Argentina began its own nuclear programme in the 1960s and was regarded as the most important country in Latin America in terms of atomic development until the German–Brazilian deal emerged.

"Argentina supports the Brazilian government in the nuclear field," declared the newspaper *La Opinion* of Buenos Aires, which is said to reflect the official line of President Jorge Videla's military-run regime. "The US offensive against Brazil, which is aimed at stopping progress on its plan with Germany to install eight more nuclear reactors, a uranium enrichment plant and a fuel reprocessing plant, is a blow which could be fatal to Brazil's nuclear industry What happens to Brazil today could happen to Argentina tomorrow."

And in a statement that must have surprised a lot of Brazilians, *La Opinion* wrote: "Brazil is not just any developing country It is a co-participant in the destinies of Argentina, in the Latin American context."

Amid the renewed debate surrounding the Brazilian–German nuclear pact, Brazilian government officials have hastened to repeat this country's justification for seeking the agreement in the first place.

- Brazil produces only 20% of the crude oil it needs every year. Its domestic coal is of low quality. Its remaining major potential hydroelectric sources are in the Amazon jungle, thousands of miles away from its centres of population and industry Therefore, Brazil must develop nuclear energy as a source of electricity
- Brazil must possess the knowhow for supplying itself with nuclear fuel. Despite a US offer to furnish already processed enriched uranium (with no transfer of technology) for Brazilian reactors, Brazil cannot run the risk of remaining dependent on foreign sources for energy (Look what happened to the United States during the Arab oil boycott, a much heard Brazilian argument goes.)
- Brazil is a peaceful country It doesn't need or want an atom bomb, and it would not divert resources from vital social and economic needs to build one. And besides, the safeguards in

the German-Brazilian nuclear agreement were approved by the International Atomic Energy Agency, with both the United States and the Soviet Union voting in favour.

Although none of the reactors or fuel processing equipment specified in the nuclear agreement actually has been built yet, the accord most definitely is being carried out, as the head of Nuclebras, Nogueira Batista, said.

More than 100 Brazilian scientists are taking specialised training in Germany, and the Brazilian government has allocated generous amounts of funds to local universities to expand programmes in nuclear-related fields of science. German atomic technicians already are working in Brazil. Adverts in newspapers are seeking secretaries fluent in Portuguese and German. Six subsidiary firms have been set up under Nuclebras to implement the agreement. These companies are to operate in areas such as nuclear technology and engineering, heavy equipment manufacturing, uranium prospecting and mining, and isotope enrichment.

Financing arrangements already have been completed for the first two 1.3 million-kilowatt German reactors that will be built in Brazil, with knowhow and components to be supplied by Germany's Kraftwerke Union. Related contracts have been signed between other German and Brazilian companies and consortiums, private as well as governmental, for site clearing and preliminary building construction.

Unofficial calculations show that over $1,000 million-worth of cruzeiros, marks and dollars have been spent or committed under the German–Brazilian nuclear agreement so far. ☐

USA

Talk about the weather

Unusual weather encourages discussion of weather modification. Colin Norman reports on the debate in the western United States

THE strange weather patterns which have brought freezing temperatures and record snowfalls to the eastern United States this winter have brought the opposite problem to many western states. A severe drought is threatening agricultural production in California and it may disrupt hydroelectric power supplies in the Pacific northwest. And in the Rocky Mountain states the snow cover is so thin that the spring runoff is unlikely to be sufficient for crop irrigation, ranching, industry and domestic needs. In short, while the east is bracing for possible floods when the thaw comes, the west is facing a debilitating drought.

One consequence of this topsy-turvy pattern is that considerable public interest has been rekindled in the use of weather modification techniques to try to increase snowfall on the western mountains before spring arrives. The most dramatic expression of such interest came in Colorado earlier this month, when the state legislature approved a bill to provide up to $250,000 for cloud seeding operations in the state. A major effort is also under way in Utah, some seedings have taken place in California, Oregon and Washington state, and an extensive long-term weather modification programme is also under discussion for the upper Colorado basin. One product so far is the generation of a good deal of local controversy.

This year's anomalous weather patterns have been caused by a stationary ridge of high pressure off the west coast, which has disrupted the normal westerly winds. Usually, the prevailing westerlies bring winter storms in from the Pacific to dump snow on the mountains in the western states, but this year the winds have been deflected northward and have looped through Canada to descend on the eastern United States. The consequences in the east have ben dramatic; in the west they have been more subtle.

Very little rain or snow has fallen in the Pacific northwest since September, and some industries which depend on hydroelectricity may face power reductions of 25% by the end of this month. Fire hazards abound in forest areas which are usually under several feet of snow at this time of the year. In California, domestic water supplies are already being rationed in Marin County near San Fransisco, and last week the Bureau of Reclamation (an agency in the Department of Interior) notified farmers in the San Joaquin Valley that their irrigation water may be cut by 75% later this year. California produces about 40% of the fresh fruits and vegetables consumed in the United States. In Utah and Colorado, snowfall has been about 30–40% of normal, and as a result ranchers are selling off cattle because they cannot get sufficient feed and the winter wheat crop may be in jeopardy.

Another, more distant problem is likely to arise because spring runoff from the Colorado Rockies supplies most of the water in the Colorado River, which in turn provides much of the irrigation and drinking water for parts of Arizona, California, Nevada and northwestern Mexico. Though water now in storage in Lake Powell behind the Glen Canyon Dam and in Lake Mead behind the Hoover Dam will be sufficient to meet downstream needs for at least a couple of years, if this year's weather patterns are repeated next winter, some serious problems could occur. Small wonder, therefore, that weather modification techniques are attracting attention. They will not provide salvation, however.

The legislation in Colorado will provide funds for massive cloud seeding operations during the rest of this winter on the western slopes of the Rocky Mountains, using silver iodide generators on the ground. Some airborne seeding will also take place in the eastern plains. In Utah, routine cloud seeding, sponsored by the Utah Water Conservation Board, has been undertaken for the past three years, and this year it is being expanded to cover nearly two-thirds of the state.

It should be noted, however, that cloud seeding can only increase natural precipitation; it cannot create snow when the conditions are not right for snowfall. Thus, the Colorado and Utah cloud seeding efforts will only be conducted if westerly winds return to bring snow clouds to the Rockies. According to a spokesman for the Colorado Water Conservation Board, the seeding programme will, at best, increase spring runoff this year by about 200,000 acre feet, an amount which will certainly not wipe out the anticipated shortages.

In a normal year, spring runoff from the Colorado Rockies into the Colorado River amounts to about 11 or 12 million acre feet. This year, Colorado officials are estimating that the runoff will be down to about 7 million acre feet.

Although any contribution from cloud seeding would be a help, environmentalists in Colorado vigorously opposed the emergency legislation when it was under consideration in the state legislature. Kevin Markey, a representative of Friends of the Earth, said last week, for example, that "it isn't emergency cloud seeding legislation, it's emergency political legislation to let everyone know that the governor and legislature are doing something". Markey argues that the time and effort spent on cloud seeding would be better devoted to water conservation programmes.

Environmentalists are particularly concerned about plans for a possible massive cloud seeding effort now under discussion in Colorado and Utah, which would entail regular seeding of winter storm clouds to try to increase spring runoff to the Colorado River each year and boost water supplies to the arid southwest. A pilot-scale seeding effort was conducted by the Bureau of Reclamation in southwestern Colorado between 1970 and 1975 to measure the impact of cloud seeding on snowfall, and to evaluate potential long-term environmental consequences of a major effort covering most of the state. The results of that pilot effort were released last month, and they are adding to the debate.

The pilot project came up with two seemingly contradictory conclusions. First, it indicated that regular seeding may increase the snowpack by about 10%. And second, it seemed to show that there was no statistical difference in the amount of snowfall on days when seeding took place compared with days of natural snowfall. Officials in the Bureau of Reclamation explain the contradiction by arguing that the seeding sometimes increased snowfall outside the target area, and residual silver iodide in the air often increased snowfall on days after seeding took place. Some seeding also took place on days when the conditions were not right for snowfall, which masked the overall effect, they claim. The ambiguous results are adding fuel to the debate about the advisability of sinking large sums into seeding this year, however.

The pilot project ended in May 1975, and discussions are now under way between officials in Utah and Colorado and representatives of the Bureau of Reclamation over the possibility of expanding the effort into a large-scale demonstration programme. The Bureau has no money in its budget to begin such a project, however, and the earliest it could be started would be the winter of 1978–79. In the meantime environmentalists, who fear possible long-term effects on wildlife, increased damage from avalanches and potential effects on rainfall downwind from the target area, will continue to urge that water conservation be supported instead.

Whatever the outcome of that debate, it will not help alleviate the anticipated drought this spring. That would require at least twice the average snowfall between now and April, a prospect which weather forecasters deem extremely unlikely. As Colorado's Governor, Richard Lam, stated when he signed the emergency cloud seeding legislation, "It's a roll of the dice". ☐

BRITAIN

Solar commitment

Britain moved another step in its efforts to implement a broad national energy policy with the announcement last week of a programme supporting the exploitation of solar power. Chris Sherwell reports

A POSITIVE but measured commitment to solar energy from the UK government; a positive but measured response from the country's solar energy lobby. That was the state of play at the end of last week after the Department of Energy (DEN) had unveiled its latest research and development programme, this time in the field of solar energy.

The announcement, neatly preceded a day earlier by a DEN junior minister's well-publicised visit to a solar heated house to reaffirm the commitment to explore alternative energies, was timed to coincide with the long-delayed publication of a report prepared for the DEN by its Energy Technology Support Unit (ETSU), based at Harwell[*]. In following earlier announcements in support of wave and geothermal power it marks another step towards comprehensive exploitation of renewable sources of energy. Reports on combined heat and power and on tidal energy are expected in the next couple of months.

The new commitment of resources to solar energy amounts to £3.6 million over four years, and is expected to bring total government expenditure in the area to about £6 million over the same period. The £3.6 million will be concentrated on three principal activities: the use of solar energy for water and space heating (the ETSU report sees this as offering the best return); the collection of additional data on solar energy, and the biological conversion of solar energy.

DEN officials were reluctant to indicate precisely how it would be allocated. An important fraction will go to work on biological conversion, but the bulk of the money will be used to accelerate the development of suitable solar power appliances. The DEN's idea is to negotiate contracts with companies with satisfactory proposals, offering them up to 50% funding to reduce the risk involved and encourage the work.

Much of the support will also complement work done by the Department of the Environment, notably through the Building Research Establishment. DEN funds will not be used to finance R&D on photovoltaic devices, however. This is already being done under the aegis of the Department of Industry.

The International Solar Energy Society in Britain (UK–ISES), though welcoming the latest development as a "good starting point" and though in agreement with the balance struck by the DEN, points out that the UK commitment compares unfavourably both in amount and in time-scale with that in other countries.

• The UK–ISES also points out that in its report released last year, *Solar Energy a UK assessment*, it estimated that solar energy could make an energy contribution of 35 million tonnes coal equivalent (mtce) by the year 2020—about 10% of total energy needs. It urged an immediate incremental budget devoted to solar energy, beginning at £2 million a year in 1976 and reaching £10 million by 1980.

Dr Walter Marshall, the DEN's Chief Scientific Adviser, citing the ETSU report, said solar energy could be making a contribution of "around 2% of our present requirements" within 25 years (some 7 mtce), an amount which could represent a "take-off point" and might be increased by a factor of about 10 over the ensuing 25 years or so. But it was hard to assess the real potential, he said, since the trends in fuel prices weren't known.

Dr Marshall paid tribute to the UK–ISES for the quality of its report. And in response to a question about the delay in the government's announcement of a programme and in publication of the ETSU report—research for it was completed 20 months ago, in July 1975—he acknowledged that he had made a mistake in not setting the wheels turning in the DEN in anticipation of a favourable verdict.

That seemed like a surprising admission. But in a country blessed with a surfeit of energy for the medium term from its oil, gas and coal resources and its existing nuclear programme, the error of judgment seems more understandable. Still, the UK–ISES emphasises the opportunities even to an energy exporter offered by solar energy investment—especially in the field of export.

The UK–ISES's enthusiasm for solar energy is not based just on faith. In January alone it received five telephone calls a day and 253 written enquiries from non-members. The newly-won enthusiasm of the DEN cannot be so complete. There the real fight is between coal and nuclear power. ☐

[*] *Solar energy its potential contribution within the United Kingdom* (London, HMSO, £3.00)

IN BRIEF

EEC safeguards progress

The complicated checking agreement between Euratom and the International Atomic Energy Agency (IAEA), reached some time ago, is now in force. With the exception of France, EEC members are now coordinating the application of IAEA and Euratom safeguards to their nuclear plants, and routine IAEA inspections will take place at the same time as Euratom inspections. There is a possibility that France will enter into its own trilateral agreement with the IAEA and Euratom. The progress on safeguards, announced last week, is expected to reduce the threat to the EEC's supplies of enriched uranium from North America. Officials in Toronto were reported last week as saying that Canada may soon resume uranium shipments to Europe.

Spacelab choice made

The European Space Agency (ESA) and NASA have chosen the 77 scientific and technological experiments to be carried on the first Spacelab mission which is scheduled for the second half of 1980. Available resources will be shared equally by NASA and ESA—61 of the experiments are European, 15 are American and one is Japanese. The flight will test both the performance of the system itself and the capability for space research. Prime targets for research will be the stratosphere and upper atmosphere, but there will also be experiments on materials processing, plasma physics, biology, astronomy and thermodynamics and lubrication. NASA and ESA next have to choose two payload specialists to work in the pressurised module; they should be selected in mid-1978.

Low-cost technology prize

The Swedish Inventors' Association is living up to its name with the announcement that it is inaugurating a highly original prize of at least $55,000 for innovations which will help to solve sociological and economic problems in the third world.

The prize will be given for their prospective, not retrospective, benefits; as it will be awarded on the hundredth anniversary of the Association's foundation, in 1986, the competition will last almost ten years. The inventors want to concentrate the competitors' efforts on certain subject-areas. The first one, announced in Stockholm recently was chosen with the firewood shortage in mind and concerns innovations related to reafforestation and the rapid production and decentralised use of wood.

Counting calories

THOMAS JUKES

A BOOK called *All Creatures Great and Small* has been on the best-seller lists for quite a while. I suppose that not all of its readers know that the verses from which the title is taken include the couplet: "The rich man in his castle, the poor man at his gate, God made them high or lowly, and ordered their estate." These lines are not best-sellers. The world is now a neighbourhood, and its inhabitants wish to shop at the same grocery as their customers whose material wants they supply. For, if manufactured products move all over the world, why should the food supply not be distributed more evenly? My tape-recorder was made in Singapore, its plug-in microphone in Japan, the cassettes in Mexico and Haiti. We grant that the race is to the swift, and the spoils to the victors, who do their best to hang on to the said spoils. However, it seems paradoxical that many people in the 'high income countries' are frantically trying to eat less, so as to live longer, and other people in impoverished lands are desperately trying to get enough food to stay alive.

Take a look at the harm done by over-eating, and at the problem of food shortages. In both cases, the central issue is calories. Too many calories lead to obesity whether they come from starch, sugar, fat or protein. Usually, however, it is carbohydrates and fats that produce obesity, with its frequent dividends of heart disease, adult diabetes and arteriosclerosis. There is a growing suspicion that risk of breast cancer and cancer of the large bowel may also be increased by high-fat diets. Obesity is not confined to inhabitants of developed countries; overeating is often one of the first responses made by people to increased availability of food in any country.

Students of diabetes have recorded that its incidence is low in populations consuming low-calorie diets, whether these are high in fat (Eskimos), high in protein (Masai) or high in carbohydrates (Indians, Zulus). Indians who move to Africa, and who then increase their caloric consumption, show a marked increase in diabetes. No longer can sleek-headed men of fat sleep soundly at night.

The diseases resulting from deprivation of food are grimmer than their counterparts in the overfed category. Calorie-deficient diets in impoverished countries are characteristically low in protein, because the cheapest sources of calories are low in protein and high in starch. Cassava meal, with a dismal 1–2% of protein, is at the bottom of the heap. It is a mainstay of many African diets. The proteins in such high-starch foods are often deficient in essential amino acids. Plants are not in business to provide animals with the good life.

The 'big three' cereals, rice, wheat, and maize, will continue to dominate the world food supply. They are deficient in lysine, tryptophan and isoleucine. Rice and wheat lack vita-A, but a million recommended daily allowances of synthetic vitamin A cost only $250. The Economic Research Service of the US Department of Agriculture, counting calories, says, "about 0.15 kilograms daily of wheat, rice, corn, sorghum, or millet would provide 500 calories. If the estimated 460 million malnourished people in the world were each provided daily with additional grain equal to 500 calories, much of the world's malnutrition would be alleviated." Where is the grain to come from? Critics of the new, high-producing strains of wheat and rice have claimed that social upheavals resulting from disruption of traditional agriculture have sometimes followed the introduction of these strains. These upheavals are accompanied by requirements for more irrigation, chemical fertilisers, and pesticides. However, for a hungry person, there is no substitute for food and, as is painfully evident in California in 1977, for a thirsty plant there is no substitute for water.

correspondence

The key to the universe

SIR,—It is always dangerous to assume that others are less intelligent than oneself. In your editorial *That Was the Weak Force, That Was* (3 February) you concede that "the initiated" found a certain amount to admire in the recent two hour programme, *The Key to the Universe*, but you add, patronisingly, "the uninitiated, which must have been 99.9% of the audience, can only have been thoroughly confused . . .". You then stand cleverly on your head and accuse the production team of one fundamental mistake: "they underestimate the serious-mindedness of the audience".

The Key to the Universe, shown on BBC2 on Thursday, 27 January, had an audience of three million; Nigel Calders' book, written in association with the programme, was soon second in the *Sunday Times* best-seller list.

We believe the public has a right to know about all aspects of science, including the esoteric, and television has a duty to inform them. It is our experience that didactic programmes attract at most half-a-million viewers: far less if made in the patronising way you advocate. I assure you that we do not underestimate the serious-mindedness of our audience and we shall continue to cater for those whom you appear to dismiss as "the uninitiated".

PHILIP DALY

Head of Science and Features,
BBC Television

Lavoisier's originality

SIR,—We have as little reason to put Lavoisier's scientific reputation on trial as had the Revolutionary Tribunal to question his loyalty to France. Gonzalez (December 9, page 504) reports that Lavoisier probably received, in 1767, a copy of John Mayow's *Opera Omnia Medico-Physica* in a shipment of 118 books ordered for his personal library.

It is much too facile to assert that "Mayow recognised the existence of oxygen, which he called *Spiritus nitro aereo*, in 1674 . . ." One might as well say that Lucretius recognised the existence of atoms 1800 years before Dalton, or Caesalpinus the circulation of blood 50 years before Harvey. If Mayow's writings were known to the 24-year-old Lavoisier in 1767, they were also known to other scientists in the preceding 93 years, yet chemistry had to wait until the 1770s for the work of Priestley, Scheele, and Lavoisier. The fact is that the idea of the *Spiritus nitro aereo* did not originate with Mayow, but derived, as Henry Guerlac has shown[1], from earlier observations concerning nitre (potassium nitrate).

As a component of gun powder, nitre was associated with explosive heat and light, but it was also associated with cold, which it produces as it is dissolved in water. An aerial spirit of nitre was therefore invoked to explain the atmospheric phenomena of thunder and lighthing, explosions so often accompanied by cold rain or hail. Since ancient times it was known that air is required for the heat of fires (for example in the use of blow pipes), and for the maintenance of animal life. Aristotle and Galen both felt that air helped to cool (to moderate) the animal body's heat. Hence in the seventeenth century an aerial spirit of nitre could be thought to provide both the heat and the coolness that the body required.

At Oxford in the years immediately preceding the young Mayow's work, Boyle and Hooke established with their vacuum pump that both a burning flame and the animal body require air; Hooke showed that the function of breathing is to supply this air rather than to squeeze by its motions the blood through the lungs, and Lower demonstrated that the blood undergoes a colour change as it passes through the aerated lungs. Much of this Mayow records in his book. He also records his own important experiments demonstrating that the combustion of certain materials, as well as respiration under certain circumstances, is accompanied by a decrease in the volume of air in an enclosed vessel. The progress of the seventeenth century scientists in understanding respiration has been lucidly summarised by Leonard Wilson[2].

Mayow was close to a discovery of oxygen in thinking that only a special part of air is involved in combustion, and that only this part is contributed by air to the blood in respiration. But his nitro-aerial spirit does not qualify as oxygen for many reasons, the most important of which are:

- ● It is not an ordinary material of definite mass or density, for Mayow asserts that it continues to exist in a vacuum, where it accounts for the conduction of light. Mayow did not claim that he had ever isolated it or measured its amount, and he did not prescribe any methods for doing so.
- ● Its qualities are too much dependent upon the circumstances impressed upon it, as for example its state of motion, which is to say that, like so much of the chemistry prior to Lavoisier, the nature of the thing was determined by too many qualifying adjectives.
- ● It is invoked to explain too wide a variety of fundamental natural phenomena, for example the nature of the sun, the presence of intense cold in the middle reaches of the atmosphere, the blueness of the sky, the nature of fire, the elasticity of air, the colours of different solid materials, and so on[3]. Incidentally, Mayow knew nothing of red blood cells and their pigment, as Gonzalez seems to imply. His explanation for the redness imparted to blood by air was that nitro-aerial particles are often of that colour, as is shown by the red distillate (nitrogen dioxide) which can be liberated by the heating of acidic nitre.

Thus it is hardly fair to assert that Lavoisier's discovery of oxygen was anticipated by Mayow, or that Lavoisier was guilty of scientific cheating in failing to give credit to him. Lavoisier's conception of oxygen was very different from Mayow's idea of the nitro-aerial spirit. And, as Guerlac has pointed out[4], Lavoisier's achievement was more fundamental even than the discovery of oxygen itself, for he was the first fully to realise that a host of material substances can exist in the gaseous state, and that the balance sheets of chemical processes must account for the materials of gases as well as of solids and liquids. Throughout his relatively short life, Lavoisier was recognised by his contemporaries as a man of exceptional genius. The day after Lavoisier was executed, the brilliant mathematician Lagrange remarked: "Only a moment to cut off that head, and a hundred years may not give us another like it"[5].

Membrane receptor–adenylate cyclase relationships

from Melvyn F. Greaves

It is now[1] generally accepted that adenylate cyclase, through the production of cyclic AMP, plays a crucial part in the recognition and transduction of regulatory signals by cells The biological responses this enzyme helps to elicit are legion gene expression (in *E. coli*), social integration and differentiation (in slime moulds); glycogen production and fat lipolysis (in mammalian cells), catecholamine activity; and (perhaps) balding in up to half the human race. The diversity of these cellular responses raises the question of how cyclic AMP can satisfy the specificity demanded by recognition–response events.

Relating adenylate cyclase activity to specialised membrane recognition events and cellular responses may not pose too great a conceptual problem with respect to mature, or 'differentiated' cells. Cyclic AMP may simply tell a cell to go faster or slower, switch on or switch off, in response to a limited number of environmental signals complementary to a restricted number of cyclase-regulating receptors. In addition, the cell's response is itself restricted qualitatively This view although simplistic is nicely supported by experiments with cholera toxin which show that stereotyped responses can be elicited by bypassing normal receptor-dependent recognition events[2]. It is also well known that cyclic AMP itself (or its dibutyryl derivative) when added to cells can also elicit the same response as the cell's normal regulators.

More serious problems are posed by the possible role of adenylate cyclase in the induction of gene programming (that is, in early 'differentiation' events) and in individual cells equipped with multiple distinct cyclase-linked hormone receptors.

A comprehensive picture of adenylate cyclase function requires much more understanding than we now have of how this enzyme's activity is integrated with other membrane and cellular events (such as ion fluxes and compartmentalisation, changes in microfilaments, membrane fluidity, activity of guanyl cyclase and phosphodiesterases and regulatory processes of gene transcription and translation

One key question is the nature of the relationship between the enzyme and receptor molecules themselves, a topic which has recently been the subject of much speculation[1-7] Figure 1 illustrates schematically the various possibilities that have been considered. It is striking that much of the debate has been dominated by the presumption that physical coupling exists between receptor and cyclase.

It is generally agreed that receptor and cyclase enzyme molecules reside mainly in opposite halves of the cell

Fig. 1 Models of possible physical relationships between hormone receptors and adenylate cyclase.

surface membrane with their active or binding sites orientated towards the aqueous phases respectively outside and inside the cell[8–11]. But the question of how they communicate remains. Are their 'ends' in contact with lipid as a lubricant or have they no physical continuity or proximity at all? What form does the modulation of cyclase activity take?

Following their extensive studies of adenylate cyclase regulation by the hormone glucagon and guanine nucleotides, Rodbell and colleagues[12,13] have suggested some answers to the last question (see also a recent review by Helmreich *et al.*[5]). They postulate that adenylate cyclase exists in three interconvertible states differing in catalytic activity and susceptibility to binding site inhibition by protonated substrate. Hormone–receptor interaction is thought to augment the normally slow (and spontaneous) transition of cyclase to that catalytic state in which it is least susceptible to inhibitory substrate. Binding of guanyl nucleotides to a regulatory site is thought to have a crucial intermediary or 'transducer' role in this hormone-facilitated transition. The favoured mechanism here, as in some other receptor systems, is allosteric interaction. Receptors are envisaged as regulatory molecules capable of exercising influence over alternative physical conformations of a partner 'effector' molecule (the cyclase enzyme or an intermediate). Hormone–receptor complexes then facilitate or stabilise that conformation of effector most commensurate with the appropriate biological response to the initiating ligand

A 'mobile receptor' hypothesis for receptor–cyclase coupling has been proposed by Cuatrecasas[4,14,15] who suggests that hormone-induced clustering of membrane receptors within the membrane facilitates contact and interaction with cyclase enzymes. This model derives its impetus from observations on lateral redistribution of exposed cell surface antigens (by antibodies), glycoproteins (by lectins) and gangliosides (by cholera toxin)[16]. A similar theoretical model has also been proposed recently by McGuire and Barber[17].

The capacity of a particular receptor to be redistributed (by a hormone, for example) will depend, amongst other things, on receptor density, hormone concentration, the valency of interactions, the association of receptor with other molecules (such as lipids of varying degree of saturation and fluidity and submembrane microfilaments) and the overall organisational symmetry of the cell in terms of its orientation, association with neighbours and ordered non-random structure of its membrane. Binding studies with labelled insulin suggest that receptors for this hormone may exist as small clusters[4,14]; however there is as yet no convincing demonstration of hormone-induced receptor clustering and there may be situations where the required redistribution is impossible

. Cuatrecasas[14] cites the instance of morphologically-polarised epithelial cells (in gut, liver and bladder for example), in which hormone receptors and adenylate cyclase may normally be concentrated at opposite sides of the cell. He argues that this situation is quite incompatible with any form of permanent structural coupling and suggests that direct interaction between receptor and enzyme could be brought about by redistribution of the mobile hormone receptor. This mechanism requires the hormone–receptor complex to undertake a rather extensive journey around the sides of the cell towards the 'distal' pole (see Fig 23 in ref. 14).

Although such large scale polarised redistribution is seen, and was of course discovered, in lymphocytes, these are motile cells with no intrinsic polarisation of receptors. Whatever mechanism of large scale redistribution is favoured[16,18], it seems rather unlikely that such membrane behaviour would be possible in non-motile tissue cells bound by various intercellular junctions. Indeed if the strict polarisation of receptors and adenylate cyclase is correct this situation provides a powerful argument against all models of receptor–cyclase interaction favouring physical coupling.

Alternative models which demand no physical coupling between receptor and cyclase enzyme must therefore be considered. Perkins[2], for example, has proposed that hormone receptors may modulate cyclase enzyme activity indirectly through a lipid 'field' effect of undefined nature.

An ingenious technique which may shed some light on receptor–cyclase relationships has been used recently by Orly and Schramm[20]. These authors (using Sendai virus) fused turkey erythrocytes, in which the endogenous beta adrenergic receptor had been inactivated by heat or N-ethylmaleimide, with Friend erythroleukaemia cells The latter have adenylate cyclase but no demonstrable beta adrenergic receptor The objective of the fusion experiment was then to 'couple' the turkey erythrocytes' beta adrenergic receptor with the cyclase derived from the leukaemic cells. Within a few minutes of fusion adenylate cyclase activity (measured by cyclic AMP formation by cell ghosts) could indeed be considerably enhanced by isoproterenol. The levels of activity recorded with a single concentration of isoproterenol (50 μM) were at least as high in the 'coupled hybrid' as in the untreated turkey erythrocyte cells incubated with isoproterenol or sodium fluoride.

This system promises to be an exciting new way of investigating lesions in membrane receptor function. Does it tell us anything about the receptor–cyclase linkage itself? Orly and Schramm interpret their results in terms of the model developed principally by Rodbell and colleagues in which the hormone receptor interacts with cyclase by way of a guanyl nucleotide binding component. However, this still leaves open the question of the physical relationship of hormone binding site, guanyl nucleotide binding site and cyclase catalytic site. One broad conclusion which seems readily available from the fusion experiments is that whatever the physical receptor–cyclase relationship, it is established with remarkable speed and apparent ease. More specifically the experiment implies that the beta adrenergic receptor is not normally coupled to an endogenous cyclase which is sub-type specific or peculiar to this receptor. This would appear to accord with the earlier studies of Rodbell[6,21] and others[3,22] who demonstrated that several distinct hormone receptors appeared to 'compete' or have access to a common pool of adenylate cyclase If correct these interpretations weaken any direct coupling models. Several other factors may also argue against a direct interaction of receptor and cyclase. Binding of some hormones (growth hormone for instance) to exceedingly few receptors, constituting a minute fraction of the cell surface area, can elicit within seconds dramatic effects of cell membrane activity such as conformational changes detected by spectroscopic methods and ion fluxes[7].

Taking into consideration the efficacy of such small numbers of receptor molecules along with the ease and speed of functional receptor–cyclase recoupling in the hybrid experiments it seems very likely that some rapid amplification step occurs between hormone receptor molecules and adenylate cyclase modulation.

Sonnenberg and Schneider have recently proposed a comprehensive model for hormone action drawing heavily on analogy with neurotransmitters[7]. They suggest that multiple membrane-associated events involving enzyme activation and microfilament changes may follow, be dependent on, and be propagated by, rapid alterations in ion fluxes and electric potential initiated by a small number of receptors. For this model to be plausible there is no reason to suppose the cyclase enzyme has, or requires, physical contact with any part of the hormone receptor molecule. This model, like its predecessors, is a working hypothesis requiring verification or denial by experiment As it stands the idea has a seductive and perhaps illusory simplicity. If its basic thesis is correct then it may in fact be even more difficult to unravel the circuitry and causal relationships involved in membrane signal transduction processes than was earlier supposed. ☐

Breakdown of superfluidity in liquid helium

from A. J. Leggett

IT has been known for more than 60 years that liquid helium (^{4}He) is superfluid below about 2 K; that is, it flows through narrow capillaries without observable friction, and, conversely, an object moving slowly through ^{4}He at low temperatures experiences practically no friction either. A major step forward in understanding this phenomenon was made by the Russian physicist Lev Landau in 1941; he showed that superfluidity is a natural consequence of certain assumptions about the 'elementary excitations' of the liquid, and predicted the critical velocity above which normal behaviour should set in. In a recent paper (*Phil. Trans R Soc.* **284**, 179; 1977) D. R. Allum *et al.* report the first unambiguous observation of this 'Landau critical velocity', thereby strongly confirming Landau's ideas. They also report some surprising and significant features of the mechanism by which superfluidity breaks down above the critical velocity.

An 'elementary excitation' is the simplest (quantised) disturbance which can be created in a given system; generally, it will carry a momentum p and an energy E which depends on p. Landau argued that at sufficiently low temperatures a heavy external body travelling through the system can experience friction only if it can create elementary excitations. However, conservation of momentum and energy prevent this happening at velocities less than the Landau critical velocity v_L given by

$$v_L = \min(E(p)/p)$$

A slight modification of the argument gives the same critical velocity for helium flowing through a capillary. In the case of a normal classical liquid it is easy to show that v_L is zero, so there is no superfluidity.

For liquid helium below 2 K, however, it is believed that the elementary excitation spectrum (the graph of $E(p)$ against p) should have the form shown in the figure. The excitations of small p (long wavelength) are quantised sound waves, or phonons, whereas those near the minimum of the curve are called 'rotons'. Originally a roton was envisaged as a quantised rotational motion of the liquid, but more recent theories have suggested some modifications to this picture and its physical nature is still somewhat obscure. The existence of rotons and more generally the correctness of the $E(p)$ curve of the figure has been confirmed both by specific-heat data and by experiments in which a neutron is scattered from the liquid by creating a single elementary excitation.

It is obvious from the figure that the minimum of $E(p)/p$ occurs near the roton minimum in the curve and is in fact given by the slope of the straight line; numerically, this corresponds to a value of v_L of about 50 m s^{-1}. At velocities higher than this emission of one or more rotons will occur, giving rise to friction. However, experiments on the flow of helium through narrow capillaries usually yield much lower (and often geometry-dependent and/or irreproducible) critical velocities, probably owing to the existence of tangles of vorticity in the liquid.

Allum and coworkers used the alternative technique of measuring the frictional drag on bodies moving through the liquid—in this case, negative ions. (A negative ion in liquid helium is believed to be a complex object composed of an electron plus the cavity it excavates for itself in the liquid and the portion of the helium which moves with it; the whole has a diameter of the order of 10 Å and a mass of about 70 helium-atom masses). When plotted as a function of electric field E, the mean velocity of the ions, $\bar{v}$, rises virtually instantaneously from zero to a value which is of order 50 m s^{-1} and coincides within the experimental error with the value of v_L predicted from the excitation spectrum. This indicates strongly that at velocities less than v_L there is indeed no frictional drag, in accordance with Landau's ideas.

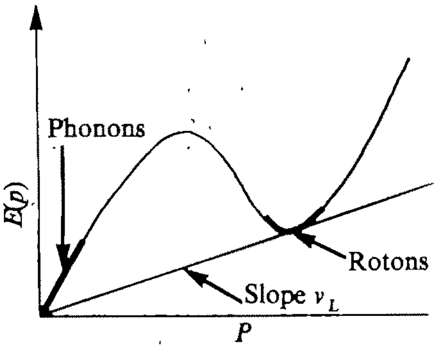

Fig. 1 Elementary excitation spectrum of superfluid helium.

A second interesting and quite unexpected result emerges from a comparison of the observed behaviour of $\bar{v}$ as a function of E with a recent theory, due to R. M. Bowley and F. W. Sheard, of the frictional drag at velocities above v_L. They showed that if the dominant process by which the ion loses energy and momentum is creation of single rotons, the quantity $v - v_L$ should be proportional to $E^{3/4}$, whereas if it is creation of pairs of rotons which dominates it should be proportional to $E^{1/3}$. For most of the range of fields studied the data fit an $E^{1/3}$ dependent; they cannot possibly be reconciled with the $E^{3/4}$ one. Thus, it seems that negative ions moving in helium create rotons only, or at least predominantly, in pairs whereas neutrons seem to have no difficulty in creating them singly! This intriguing result seems certain to stimulate further research, both experimental and theoretical, into the physical nature of rotons. ☐

Dynamic Stark splitting

from Peter Knight

WORKERS in fields other than quantum optics or atomic physics may be surprised to hear that resonance fluorescence, that classic phenomenon of early quantum physics, has shrugged off its antiquarian associations to become a major and intensively studied new research problem. The rejuvenating influence has been the tunable laser. Unlike life, 'undressed' atoms, those old-fashioned atoms bathed in a weak radiation field, become very much more interesting when 'dressed' by an intense resonant radiation field. The interest has shifted from a purely spectroscopic analysis of atomic structure to the basic mechanisms by which any atom interacts with radiation.

At low excitation intensities the process of resonance fluorescence is well understood: if the excitation field is monochromatic, the atom absorbs a photon at the excitation frequency, and energy conservation demands that the emitted photon have the same frequency. One-photon processes are dominant. The emitted fluorescence has the same spectral profile, and in particular the same narrow width, as the excitation. Resonance fluorescence with a spectral width narrower than the natural linewidth has been observed for the first time, by Gibbs and Venkatesan at Bell Laboratories (*Opt. Commun.* **17**, 87; 1976), using the dye-laser excited 2,852 Å ^{24}Mg transition, and by Wu, Grove and Ezekiel at the Massachusetts Institute of Technology (*Phys. Rev. Lett.* **35,** 1426; 1975), using the 5,890 Å D line of sodium.

Of more interest is what happens to the fluorescence process as the laser intensity increases. In a strong resonant field, non-linear scattering occurs. Multiphoton processes become as important as single photon processes. Energy conservation holds overall for the multiphoton process, but the fluorescence spectrum is no longer monochromatic. The atom can coherently interact many times with the laser field before spontaneously radiating a photon. Clearly we can no longer rely on the conventional low-order perturbation theory of resonance fluorescence.

An atom of principal transition frequency ω_0 interacting with a coherent laser field of frequency ω is stimulated to emit and reabsorb photons. The rate at which transitions are coherently induced between the two atomic levels is known as the Rabi frequency and is proportional to the square root of the laser intensity. One can think of the atom heuristically as a damped driven quantum oscillator, the damping being supplied by spontaneous emission and the driving force by the interaction with the laser field. At low intensities, spontaneous emission is more important than stimulated processes, and the atom behaves as an over-damped oscillator, radiating a field centred upon the driving frequency. At higher intensities the stimulated Rabi nutational frequency can exceed the spontaneous emission rate and the atom behaves just like an under-damped oscillator. The Rabi oscillations show up not only in the population of the atomic levels (the inversion) but also as a modulation of the quantum dipole moment. This in turn leads to sidebands emerging in the spectrum of the emitted radiation, and this so-called "dynamic Stark splitting" has attracted a great deal of interest.

The basic theory to describe monochromatic strong-field resonance fluorescence was developed by Mollow some time ago (*Phys. Rev.* **188,** 1969; 1969). Mollow calculates the emission spectrum directly from the Fourier transform of the atomic dipole moment correlation function. This correlation function (if steady state is assumed) can be expressed in terms of the atomic inversion and dipole moment produced by the strong laser field interaction. Qualitatively we expect to find a strong-field fluorescence spectrum with a central spontaneous emission line, and two subsidiary sidebands separated from the central component by the Rabi frequency. Mollow's theory demonstrates just how this happens in detail and predicts a spectrum made up of three Lorentzian-shaped lines; a strong central component at the laser frequency and two sidebands with peak intensities 1/3 that of the central line (see Fig. 1). The central component has the natural width Γ. The sidebands have a width 3Γ/2 and are displaced from the central peak by the Rabi frequency Ω, which is proportional to the amplitude of the laser electric field strength. Many authors have contributed to the detailed understanding of the fluorescence spectrum, but the broad features are all contained in the Mollow theory.

Experimental work by three groups all using dye-laser excited atomic beam methods broadly confirm Mollow's original prediction. Schuda, Stroud and Hercher (*J. Phys.* **B7,** L198; 1974), Ezekiel *et al.* (Wu, Grove & Ezekiel (*op. cit.*), and Walther and coworkers, at Köln and München (*Z. Physik.* **A278,** 205; 1976) have all observed the triplet splitting as the intensity increases. Certain asymmetries of the lineshape, almost certainly due to optical pumping effects extraneous to the basic phenomenon, have been noted and in part eliminated by careful preparation of the atoms by circularly polarised light.

Theoretical interest seems now to be concentrating on the role of the state of coherence of the incident laser radiation in these basically multiphoton processes. Intensity fluctuations will obviously be important as a 'smearing-out' effect: the a.c. Stark splitting is proportional to the square root of the instantaneous intensity. Similarly, phase fluctuations will create jitter in atomic dipole moments and correlation functions will be additionally damped. To analyse the effects of a partially coherent field, and to generalise the purely monochromatic field approach of Mollow is not easy. The detailed dynamics of an atom interacting with an intense field are described by the optical Bloch equations (analogous to nuclear magnetic resonance equations of motion). These equations can be solved straightforwardly by a Laplace transform technique if the radiation field is purely monochromatic, but this is not directly applicable if the field is partially coherent. Neither do traditional Bloch–Wangsness relaxation methods apply, because the laser power is too high.

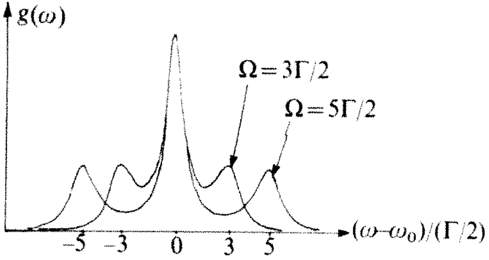

Fig. 1 The emission spectrum $g(\omega)$ for a resonantly driven two-level atom for two different laser intensities according to Mollow's theory.

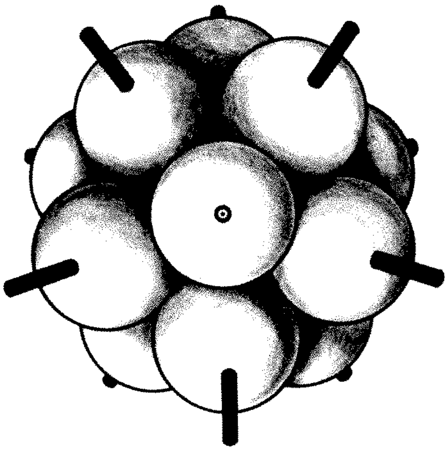
Recently, a non-perturbative theory of atomic relaxation in the presence of intense partially coherent radiation has been developed by Eberly (*Phys. Rev. Lett.* **37,** 1387; 1976) and applied to the theory of resonance fluorescence. By including stochastic phase and amplitude fluctuations of the laser directly in the equations of motion for the atomic dipole and inversion operators and assuming a simple exponential damping of first order phase and amplitude correlations, he describes how the Mollow theory of resonance fluorescence is modified by the finite bandwidth of the laser field. He is also able to include the effects of the interferometer analysing the radiated field spectrum. His results indicate that laser phase and amplitude fluctuations can alter the shape of the fluorescence spectrum in an unexpected and non-additive way. Amplitude fluctuations increase the height of the centre peak relative to the sidebands; phase fluctuations lower it. Eberly's results have been confirmed by Agarwal (*Phys. Rev. Lett.* **37,** 1383; 1976) using much more complex and physically less transparent methods. Agarwal goes on to look at the effect of laser bandwidth on the statistics of the emitted radiation. It is known from the work of Walls and others (Carmichael & Walls *J. Phys.* **B9,** 1199; 1976) that the emitted radiation should exhibit a fundamentally quantum feature called "antibunching", in contrast to the photon bunching familiar from the Hanbury-Brown Twiss experiment. Agarwal's results indicate that this too is affected by the laser bandwidth. ☐

ΦX174 sequenced



from Maria Szekely

A GREAT advance in DNA research is reported in this issue: the first complete nucleotide sequence of a DNA genome has been established by Sanger's group in Cambridge (see page 687 of this issue of *Nature*). For the first time it is possible to look at a viral genome as a giant molecule of known structure, all functions of which should be accessible to interpretation in terms of its molecular structure.

The small coliphage ΦX174 is particularly suitable for studies on the structural features underlying the complex processes of gene expression. It has a number of unusual characteristics—its small DNA possesses an unexpectedly high information content and seems to exploit every structural possibility to control gene expression. The single-stranded circular DNA genome of 5,375 nucleotides codes for nine proteins, some of which have been directly sequenced. The amino acid sequence of the others can be deduced from nucleotide sequence data. Genetic and physical maps of the genome have been constructed and have been correlated recently by Weisbeek *et al.* (*Virology* **72,** 61; 1976) who estimated the probable length of each gene. But there is a discrepancy between the calculated coding potential of some regions in the physical map and the proteins produced. Replication and transcription of the genome have also been studied extensively, with some unexpected results. Baas *et al* (*J. molec. Biol.* **102,** 633; 1976) located the origin of replication in the middle of a structural gene coding for protein A. Hayashi *et al.* (*Proc. natn. Acad. Sci. U.S.A.* **73,** 3519; 1976) reported the presence of two mRNAs covering the *A* gene region, only one of which was functionally active. The complete sequence has now provided a sound structural basis for these peculiarities.

ΦX174 DNA has been the subject of nucleotide sequence studies from early on. Practically all DNA sequencing techniques have been applied to this molecule, and some have been actually worked out on this DNA. Five years ago classical degradation techniques only allowed the determination of sequences of about 50 nucleotides which made the task of resolving the primary structure of DNA molecules seem much more difficult than the sequencing of RNA. Introduction of new techniques, making use of primed synthesis of highly-labelled complementary strands on ΦX DNA template greatly extended these possibilities. Eventually the new highly efficient 'plus and minus' technique of Sanger and Coulson (*J. molec. Biol.* **94,** 441; 1975) which allows 150–200 nucleotide long sequences to be read directly, made it possible to produce a complete sequence of the ΦX genome a year after the first (and so far only) complete sequence of an RNA genome had been determined (Fiers *et al. Nature* **260,** 500; 1976).

Together with these sequence determinations, information on characteristic structural features of some functional sites of the DNA has also contributed to the construction of a 'chemical map' of the ΦX genome. 5′-terminal sequences of three mRNAs produced *in vitro* have been determined by Smith and Sinsheimer (*J. molec. Biol.* **103,** 699 and 711; 1976); ribosome binding sites on mRNAs corresponding to the initiation of genes *B*, *J*, *F* and *G*, have been sequenced by Ravetch *et al.* (page 698 of this issue). Homologies with other promoter and terminator sequences as well as the presence of purine tracts at all ribosome recognition sites helped to locate each gene in the sequence. At the same time, these homologies confirmed that the structure suggested for these control signals is generally valid.

The interesting question now arises of how the peculiar properties of ΦX can be interpreted in the knowledge of the primary structure. The most intriguing aspect is how the very high information content can be compressed into a small DNA molecule.

It now seems that this phage has several ways of ensuring the most economical use of its DNA. The most spectacular discovery has already been reported—the same stretch of DNA can code for two proteins which are translated in different reading frames (*News and Views* **264,** 11; 1976). In 1976 Barrell *et al.* (*Nature* **264,** 34) found that the complete *E* gene was contained within the *D* gene region. A similar situation is reported now for genes *B* and *A*. Two papers in this issue provide evidence that gene *B* is contained within the region of gene *A*: Brown and Smith (page 695) locate the ribosome binding site for gene *B* within the gene *A* region, and Smith *et al.* (page 702) assign mutants in gene *A* and gene *B* to different reading frames in the overlapping area.

Another DNA stretch which fulfils multiple functions was found at the beginning of the *A* gene, where the 3′-terminal part of an mRNA which had started at an earlier promoter overlaps with the beginning of the mRNA for the *A* gene. The sequence of this DNA stretch suggests that a specific hairpin loop structure may be involved in the control mechanism which provides within this overlap a termination signal for one mRNA without interfering with the initiation of transcription of another mRNA. Readthrough at the termination signal may explain Hayashi's finding of two mRNAs covering this area. Two more overlaps occur at the initiation sites of proteins C and J, where the initiation codons overlap with the termination codons of the previous cistrons. The purine tracts preceding the initiation codon serve thus both as recognition sites for ribosomes and as coding sequences for another protein. Gene *A* seems the most versatile part of the genome: in addition to the multiple functions listed above, it also contains the origin of replication, and thus recognition sites for the proteins involved. The exact site of the origin has not been located, but the region in gene *A* which contains this site has been defined. Its sequence is less characteristic than could have been anticipated, it shows no symmetry or secondary structure, only a probable specific arrangement of an A–T rich stretch between the G–C rich stretches.

The multifunctional character of ΦX DNA may be a unique property displayed only by a few very small DNA viruses. Overlapping termination and initiation codons have also been detected, however, in the tryptophan messenger of *Escherichia coli* (Platt & Yanofski *Proc. natn. Acad. Sci. U.S.A.* **72,** 2399; 1975), the possibility thus exists that at least some of the above ways to compress more information into DNA may be of more general significance. If this were so, our ideas about the coding potential of DNA genomes would have to be fundamentally altered.

X-ray laser quest

from I. J. Spalding

For the alchemists it was the Philosopher's Stone, for the fusion specialist it's 'scientific break-even', but for some laser enthusiasts their chosen—and one hopes attainable—goal is the X-ray laser. The advent of high brightness, uniquely monochromatic, coherent light sources in the visible and infrared regions of the electromagnetic spectrum has already completely transformed many interferometric, scattering and spectroscopic techniques, and has opened up prospects for entirely novel applications. One might expect that the development of coherent X-ray sources would similarly revolutionise such tasks as high-resolution, time-resolved X-ray diagnostics and crystal structure determination.

Why is this goal difficult to achieve? One fundamental problem lies in the short life time of the upper levels of interest: the spontaneous life time for a 10 keV K–L transition in copper metal might typically be 10^{-15} s, implying the gargantuan pumping requirement of ~1 watt per atom! Several ingenious schemes have been proposed to provide such high pumping rates. These include Gudzenko and Shelepin's proposal for rapid recombination in a dense (laser-produced) plasma, Duguay and Rentzepis' photoionisation scheme, and McCorkle's suggestion for sweeping a high-current ion beam at the speed of light along an obliquely-oriented foil target.

Not surprisingly, such novel physical conditions may pose unusual theoretical problems. Bonifacio, Hopf, Meystre and Scully have recently reviewed quantum electrodynamic modifications to conventional small-signal gain theory which become necessary in a travelling wave X-ray laser where the pump behaves as a delta function swept at the velocity of light along the active medium. Depending on how fast the population inversion decays compared with the atomic polarisation, the amplification may be substantially smaller than that anticipated from semi-classical (Maxwell–Schrödinger) theory. Happily, large-signal pulse amplification becomes more favourable in the non-linear regime since coherence brightening, super radiant effects and power broadening (that is, broadening of energy levels due to the e.m. electric field) are predicted to reduce saturation effects.

Most X-ray laser experimenters have concentrated their attention on transitions in laser-generated plasmas at wavelengths in the extreme ultraviolet, where detailed numerical computations have shown that reasonable gains are achieveable using the high power lasers now available. The plasma conditions and computer codes required are similar to those of interest in laser fusion. In 1974 Irons and Peacock reported population inversion between states of principal quantum number $n=2$–5 in an expanding low-density C^{+5} laser-produced plasma, and recently Dewhurst *et al.* (*Phys. Rev. Lett.* **37**, 1265; 1976) have demonstrated inversion of the $n=3$ to $n=2$ transition of CVI at 182 Å at densities which it is claimed are sufficiently high to permit (length) scaling to useful gains.

This approach relies on an extremely rapid expansion and cooling of a fully ionised plasma; recombination then leads to a preferential population of the upper states, and hence an inversion. In the work of Dewhurst *et al.* the target was a 5.3-μm diameter carbon fibre supported vertically at the focus of a 0.15 J Nd–glass laser pulse of duration 1.4×10^{-10} s. The fibre was first shattered by a carefully chosen prepulse, and then irradiated by the main pulse having a contrast ratio exceeding 10^4. The width of the main pulse was determined by the time needed to heat and ionise the dense cold plasma formed by the prepulse. The presence of inversion was deduced from the relative intensities of (time averaged) Lyman series lines, photographically recorded by an absolutely calibrated 2 m grazing incidence spectrograph. Space-averaged spectra could be obtained using a single laser shot, but an average of 30 exposures was required when the radial resolution was narrowed to 100 μm. The radial variation of L_α, L_β, and L_λ, intensities accords well with their numerical model, and thus they compute a maximum gain-length product of 2×10^{-2} for their experiment. They estimate that a 100 J laser should permit a gain-length product of ~10, and so permit laser operation in a travelling-wave mode, and that the gain should vary as $Z^{7.5}$, where Z is the charge number of the ion. However for $Z\geqslant13$ laser compression would be needed to achieve the very high densities (and small radii) required.

Although these and other developments are encouraging it should be noted in conclusion that it seems unlikely that regenerative feedback in the extreme ultraviolet will be possible, and that the shortest wavelength coherent sources are currently produced by non-linear optical conversion in solids and gases. (The record is temporarily held by a group at the US Naval Research Laboratory, who have in this way generated 380 Å, the 28th harmonic of the Nd–YAG 1.06 μm laser.) □

Transform faults

from Peter J. Smith

When Wilson (*Nature* **207**, 343; 1965) originally defined transform faults, he suggested that the transform faults offsetting the oceanic ridges were directly inherited from the pattern of continental rifting which had led to the formation of the relevant plate boundary. But many Earth scientists have never been entirely happy with this view of the origin of ridge-to-ridge faulting. Nor have they been happy with the lumping together of all transform faults into a single class—a class which fails to distinguish between, for example, the long San Andreas fault and the shortest of faults offsetting the mid-Atlantic ridge.

A distinction is now made by Gilliland and Meyer (*Geol. Soc. Am. Bull.* **87**, 1127; 1976) who divide transform faults into 'boundary transform faults' and 'ridge transform faults'. Boundary transform faults are major faults genuinely inherited from the original rifting which gives rise to a plate and "are necessary initially to permit differential movement between discrete plates". They are thus contemporaneous with the formation of the plate. They are most likely to be ridge-to-trench faults and least likely to be ridge-to-ridge, although the latter are not excluded. Examples of boundary transform faults quoted include the Alpine, Denali, New Guinea, Philippines and San Andreas faults and the Ninetyeast ridge.

By contrast, ridge transform faults occur only along oceanic ridges and are thus always ridge-to-ridge types. They are not inherited from initial rifting but (as wax models show) result from the spreading process; that is, they are contingent upon the existence of spreading. They are secondary features and thus not generally contemporaneous with plate formation. Indeed, in theory they are not necessary for plate boundary formation at all and do not always exist when spreading rates are very low.

A weak point in the argument seems to arise from the need to admit ridge-to-ridge faults into both major categories. For example, Gilliland and Meyer regard the San Andreas fault as a boundary transform fault, although they concede that "its real nature is not by any means certain". Apart from the size of this particular fault and the fact that it impinges on land, the precise grounds for distinguishing it from ridge-to-ridge faults in the ridge transform fault category are not made entirely clear.

Nucleotide sequence of bacteriophage ΦX174 DNA

F. Sanger, G. M. Air*, B. G. Barrell, N. L. Brown†, A. R. Coulson, J. C. Fiddes, C. A. Hutchison III‡, P. M. Slocombe§ & M. Smith¶

MRC Laboratory of Molecular Biology, Hills Road, Cambridge CB2 2QH, UK

A DNA sequence for the genome of bacteriophage ΦX174 of approximately 5,375 nucleotides has been determined using the rapid and simple 'plus and minus' method. The sequence identifies many of the features responsible for the production of the proteins of the nine known genes of the organism, including initiation and termination sites for the proteins and RNAs. Two pairs of genes are coded by the same region of DNA using different reading frames.

THE genome of bacteriophage ΦX174 is a single-stranded, circular DNA of approximately 5,400 nucleotides coding for nine known proteins. The order of these genes, as determined by genetic techniques[2–4], is *A–B–C–D–E–J–F–G–H*. Genes *F*, *G* and *H* code for structural proteins of the virus capsid, and gene *J* (as defined by sequence work) codes for a small basic protein that is also part of the virion. Gene *A* is required for double-stranded DNA replication and single-strand synthesis. Genes *B*, *C* and *D* are involved in the production of viral single-stranded DNA: however, the exact function of these gene products is not clear as they may either be involved directly in DNA synthesis or be required for DNA packaging, which is coupled with single-strand production. Gene *E* is responsible for lysis of the host.

The first nucleotide sequences established in ΦX were pyrimidine tracts[5–7] obtained by the Burton and Petersen[8] depurination procedure. The longer tracts could be obtained pure and sequences of up to 10 nucleotides were obtained. More recently Chadwell[9] has improved the hydrazinolysis method to obtain the longer purine tracts. These results are included in the sequence given in Fig. 1.

More extensive ΦX sequences were obtained using partial degradation techniques, particularly with endonuclease IV (refs 10 and 11). Ziff *et al.*[12,13] used this enzyme in conditions of partial hydrolysis to obtain fragments 50–200 nucleotides long which were purified as ^{32}P-labelled material by electrophoresis on polyacrylamide gels. The fragments came from the same region of the genome and the sequence of a 48-nucleotide long fragment (band 6, positions 1,047–1,094) was determined using mainly further degradation with endonuclease IV and partial exonuclease digestions.

Another 50-nucleotide long fragment was obtained by Robertson *et al.*[14] as a ribosome binding site. The viral (or plus) strand DNA of ΦX has the same sequence as the mRNA and, in certain conditions, will bind ribosomes so that a protected fragment can be isolated and sequenced. Only one major site was found. By comparison with the amino acid sequence data it was found that this ribosome binding site sequence coded for the initiation of the gene *G* protein[15] (positions 2,362–2,413).

At this stage sequencing techniques using primed synthesis with DNA polymerase were being developed[16] and Schott[17] synthesised a decanucleotide with a sequence complementary to part of the ribosome binding site. This was used to prime into the intercistronic region between the *F* and *G* genes, using DNA polymerase and ^{32}P-labelled triphosphates[18]. The ribo-substitution technique[16] facilitated the sequence determination of the labelled DNA produced. This decanucleotide-primed system was also used to develop the plus and minus method[1]. Suitable synthetic primers are, however, difficult to prepare and as DNA fragments generated by restriction enzymes are more readily available these have been used for most of the work reported here.

Another approach to DNA sequencing is to make an RNA copy using RNA polymerase with α-^{32}P-labelled ribotriphosphates and then to determine the RNA sequence by more established methods. Blackburn[19,20] used this approach on intact single-stranded ΦX and on fragments obtained by digestion with endonuclease IV or with restriction enzymes. Sedat *et al.*[21] were extending their studies on the larger endonuclease IV fragments and their results, taken in conjunction with the transcription of the DNA fragments[20], amino acid sequence of the F protein[22], and the plus and minus method results, made it possible to deduce a sequence of 281 nucleotides (positions 1,016–1,296, Fig. 1) within the *F* gene[23]. Transcription of *Hin*dII fragment 10, amino acid sequence data in the *G* gene, and the plus and minus method using *Hin*dII fragments 2 and 10 as primers, gave a sequence of 195 nucleotides (positions 2,387–2,582, Fig. 1) at the N terminus of gene *G* (ref. 24).

The 'plus and minus' method

Further work on the ΦX sequence has been done using chiefly the plus and minus method primed with restriction fragments. Figure 2 shows the various restriction enzymes used and the fragment maps for each (refs 25–30 and C.A.H., submitted for publication, and N.L.B., C.A.H. and M.S., submitted for publication).

Figure 1 shows the combined results of the sequence work to date. The sequence is numbered from the single cleavage site of the restriction enzyme *Pst*I. As with other methods of sequencing nucleic acids, the plus and minus technique used by itself cannot be regarded as a completely reliable system and occasional errors may occur. Such errors and uncertainties can only

Fig. 1 A provisional nucleotide sequence for the DNA of bacteriophage ΦX174 *am*3 *cs*70. Solid underlining indicates sequences that are fully confirmed; sequences with no underlining probably do not contain more than one mistake per 50 residues. Broken underlining indicates more uncertain sequences. Restriction enzyme recognition sites are indicated (for key to single letter enzyme code see legend to Fig. 2), as are mRNA starts and protein initiation and termination sites. Nucleotides 4,127 to 4,201 have been independently sequenced by van Mansfield *et al.*[illegible]. The *am*3 codon is at position 587.

be eliminated by more laborious experiments and, although much of the sequence has been so confirmed, it would probably be a long time before the complete sequence could be established. We are not certain that there is any scientific justification for establishing every detail and, as it is felt that the results may be useful to other workers, it has been decided to publish the sequence in its present form.

As template we have used both the viral (plus) and complementary (minus) strands of ΦX. Usually it is possible to determine a sequence with a single primer starting at about 15–100 nucleotides from the appropriate restriction enzyme site. In a particularly good experiment the sequence can be read out to 150–200 nucleotides but the results may become less reliable. Most sequences have been derived by priming on both strands; this allows more confidence than when only one strand could be used.

A useful method for confirming runs of the same nucleotide is depurination of ^{32}P-labelled small restriction enzyme fragments or of products of the DNA polymerase priming experiments (ref. 31 and N.L.B. and M.S., in preparation). The most satisfactory way of confirming the DNA sequences is through amino acid sequence data. As the methods used are entirely unrelated, the results of the two approaches complement each other very well and therefore complete sequences can usually be deduced from incomplete data obtained by each method. The complete sequence of genes *G* (ref. 32), *D* (ref. 33), *J* (ref. 33 and Freymeyer, unpublished) and most of *F* have been obtained in this way.

Many of the sequences in Fig. 1 have been amply confirmed and are regarded as established: these are indicated in the figure by underlining. Some sequences are considered to be reasonably accurate and probably contain no more than one mistake in every 50 nucleotides. Sequences that are particularly uncertain—either because of lack of data or conflicting results—are also indicated in Fig. 1.

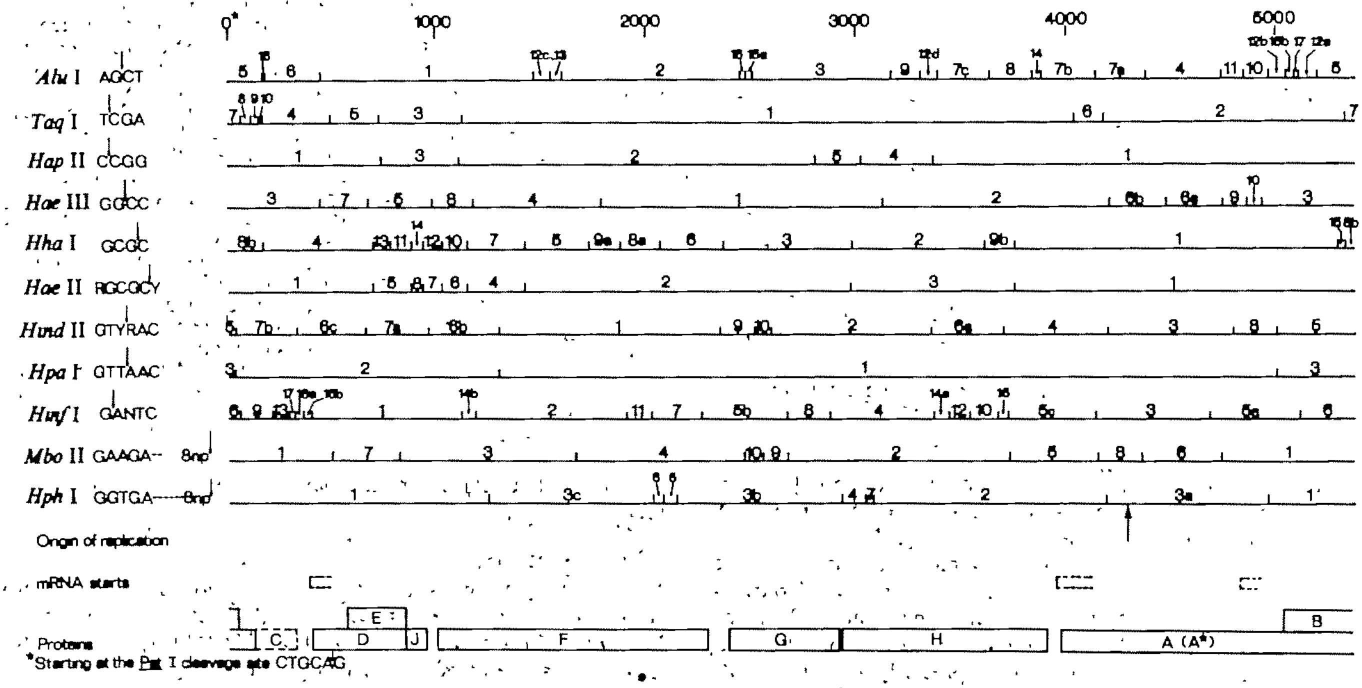
In considering the sequence of ΦX174 as a functional unit it is convenient to begin in the region between the *H* and *A* genes and to continue around the DNA in the direction of transcription and translation.

A promoter and terminator

Sinsheimer *et al.*[34,35] and Axelrod[36] have determined the sequences of the 5′ end of three ΦX *in vitro* mRNA species and have located them on the restriction map. These sequences have been identified on the DNA sequence and one of them (AAATCTTGG) is found only at position 3,954 at which an *in vivo* unstable mRNA start has been located[37]. The sequence to the left of this has some characteristics of typical *E. coli* promoters[38] in that five out of the 'ideal' TATPuATPu residues are present. Nearby, to the right of this mRNA initiation, however, is the sequence TTTTTTA which is similar to sequences found at the 3′ ends of a number of mRNAs (see ref. 39) and seems a likely signal for mRNA termination. The presence of a rho-independent termination site in this approximate position has been suggested[36,37], but the relative positions of the initiating and putative termination signals is rather surprising since the terminator for one mRNA would be expected to precede the initiator for the next. One possibility is that the T_4A might be acting as an 'attenuator' involved in the control of mRNA production in a similar manner to that suggested for the tryptophan operon by Bertrand *et al.*[40]. If indeed it were acting as a transcription terminator one would expect a small RNA of 20 nucleotides to be produced, but no such product has yet been detected. Recent work, however, (Rosenberg, unpublished and ref. 41) indicates that termination may require the presence of a base-paired loop structure before the termination site. From the DNA sequence such a loop is probably present before the T_4A sequence, but in mRNA starting from the initiation site at position 3,954 this loop is not formed (Fig. 3). Therefore mRNA that had started at an earlier promoter and extended through the *H* gene would be expected to terminate here, whereas mRNA newly initiated at position 3,954 would not. This could be a way in which the phage has economised on the use of DNA—by having the ends of the two mRNAs overlapping.

The A protein

Where the amino acid sequence is available there is no problem in relating the DNA sequence to its coding properties, but it is



*Starting at the Pst I cleavage site CTGCAG

Fig. 2 Fragment maps of restriction enzymes used in the sequence analysis of ΦX174 *am*3 RFI DNA. Fragment maps of ΦX174 have been prepared for *Hin*dII (R), *Hae*III (Z) and *Hpa*I+II by Lee and Sinsheimer[35], *Hin*HI and *Hap*II (Y) by Hayashi and Hayashi[36], and for *Alu*I (A) by Vereijken *et al.*[37] and for *Pst*I (P) by Brown and Smith[38]. B.G.B., G.M.A., C.A.H. and D. Jaffe prepared the *Hin*fI (F) map, C.A.H. the *Hph*I (Q) map, and Jeppesen *et al.*[33] the *Hha*I (H), *Alu*I, *Hae*II and *Hap*II maps by using a rapid method depending on priming with DNA polymerase. A rapid two-dimensional hybridisation technique has been developed by C.A.H. (submitted for publication) and recently used for mapping *Mbo*II (M) (N.L.B., C.A.H., and M.S., submitted for publication) and *Taq*I (T)[39]. *Hha*I and *Hin*fI maps have also been prepared by Baas *et al.*[33].

more difficult to do so in the absence of such data, as is the case for the A protein. One way of identifying the reading phase of the DNA is from the distribution of nonsense codons. Over a sufficiently long sequence that is known to be coding for a single protein there is usually one phase that contains no nonsense codons, and this is identified as the reading phase. This requires completely accurate determination of the DNA sequences however: omission of a single nucleotide may give completely erroneous results. Another approach is possible in the case of ΦX. The results with the *F* and *G* genes[13,34,35] showed an unexpectedly high frequency of codons ending in T. Therefore in a coding region there is a tendency for every third nucleotide to be a T and it is then possible to define the reading phase. Figure 4 illustrates how this characteristic was used to help determine the reading phase for the A protein and to identify its initiation codon at position 3,973. In a similar way the distribution of Ts may be used to identify errors in the DNA sequence, provided that such errors occur only infrequently.

A different approach to identifying the initiation site and reading phase in a coding sequence is by looking for a characteristic 'initiation sequence'. Shine and Dalgarno have shown that a common feature of ribosome binding sites is a number of nucleotides (at least three) preceding the ATG that are capable of forming base pairs with a sequence at the 3′ end of 16S rRNA[42,43]. All of the known initiation sites in ΦX174 that have been identified by direct amino acid sequencing (for the F, G, H, J and D proteins) satisfy this criterion (see Table 2) and the fact that the sequence preceding the ATG in position 3,973 also has this characteristic supports its identification as the initiation site for the A protein.

If, as has been suggested[37], some mRNA from the previous promoter does extend beyond the hairpin structure, initiation of A protein synthesis may be controlled by the inclusion of the region complementary to the 16S rRNA in the hairpin loop. This could explain the presence of two types of mRNA covering the *A* cistron, as suggested by Hayashi *et al.*[37]—one unstable and active and the other stable but inactive. The former would be intiated at the A promoter, the latter at an earlier promoter and result from 'read-through' at the terminator. The postulated reading frame for the A protein was confirmed by sequencing amber mutants mapping in the N-terminal region of gene *A*. *am*86 proved to be a C→T change at position 4,108 and *am*33 a C→T change at position 4,372. These both result in formation of an amber codon (TAG) in the same reading frame as the proposed initiating ATG and the sequence continues to the termination codon at position 133. The A protein, which is the largest coded by ΦX174, is thus 512 amino acids long with a molecular weight of 56,000, in good agreement with SDS gel estimations (see refs 4 and 44). The A* protein, with a molecular weight of about 35,000, is believed to result from an internal translational start in the *A* gene, in the same reading phase[45]. From consideration of possible ribosome binding sequences[42,43] the ATG in position 4,657 seems to be the most likely initiation site for the A* protein.

The origin of replication

The origin of ΦX viral strand DNA synthesis has been located in gene *A*, in restriction fragment Z6b (ref. 46). This origin, while

Fig. 3 Potential secondary structure at the *A* mRNA start.

*These figures refer to the last five codons of the previous line and the first five of the next line.

Fig. 4 Identification of the initiation codon for the A protein. Sequences of 30 nucleotides in the region in which the initiation was expected were written down and arbitrarily marked off in triplets. The number of T residues in the first position in each triplet was then counted and listed, and similarly the number of Ts in the second and third positions. The marked preference for Ts in position 3 in the last two lines, as compared with the first two lines, suggests that they are coding for protein and that the triplets are correctly marked off. The most likely initiation codon for the A protein is the ATG in position 3,973.

coding for part of the A protein, probably corresponds to the position of the plus strand nick made by the same protein[44]. Gaps in this region that are found in replicating double-stranded (RF) DNAs are probably related to the position of the nick. Eisenberg *et al.*[47] have investigated such gaps by depurination analysis and identified, in particular, the product C_4T. The sequence CTC_4 is found in position 4,285 (Fig. 1) and the location of the origin in this region agrees precisely with the results of Baas *et al.*[44]. It is not possible at present to identify the actual position of the origin nick. The region shows no apparent secondary structure or symmetrical sequences, although there is an AT-rich region (4,298–4,307) between two GC-rich regions which might be of significance. Such a region is found near the origin of replication of SV40 DNA (ref. 48).

B promoter

The second of the mRNA 5′ sequences (AUCGC)[34] has been mapped in restriction fragment R8 (Fig. 2), which starts about 300 nucleotides on from the proposed A* initiation. The sequence ATCGC is found at positions 4,832 and 4,888 in Fig. 1. The only way we can choose between them at the moment is that the second is preceded by the sequence TACAGTA (position 4,877), which is more akin to sequences found in known promoters[38] than are sequences preceding the other possible mRNA start. Irrespective of which of these sequences is used, the mRNA has a long 'leader' sequence (232 or 176 nucleotides) before the next proposed initiation codon (gene *B*).

Table 1 ΦX174 coding capacity

Gene	Protein molecular weight from SDS gels*	Number of nucleotides (Fig. 1)	Protein molecular weight from sequence information
A	55,000–67,000	1,536	56,000

*See ref. 4

†Values in parenthesis are overlapping sequences and therefore not included in the addition to obtain the total length of DNA.

‡These values are calculated from the amino acid sequence (in the case of B deduced from the nucleotide sequence). The others are derived using the formula

$$\text{Protein molecular weight} = \frac{\text{No. of nucleotides}}{3\times 0.00915}$$

The B protein

From a study of the ribonuclease T_1 digestion products of the ribosome binding sites of ΦX mRNAs[49], it was possible to identify an initiating ATG in position 5,064. From the genetic map[2,3], this would be expected to be gene *B* but, as discussed above, the A protein coding sequence extends right through this region, past the *Pst* site at residue 1 in Fig. 1, and terminates at residue 133. The initiating codon contained in the ribosome-protected sequence is, however, out of phase with the A protein reading frame. The proposed B protein coding sequence is one nucleotide to the left of the A protein phase, and continues until a termination codon occurs at position 49. Therefore the B protein coding sequence is totally contained within the *A* gene. These reading frames have been confirmed by sequencing mutants in genes *A* and *B* (*am*16, N.L.B. and M.S., in preparation; *am*18, *am*35, *ts*116 (ref. 50). Since the B protein has not been purified no protein sequence data is available. The complete amino acid sequence can be predicted from the DNA sequence however. The protein is 120 amino acids long with a molecular weight of 13,845 (including the N-terminal Met). The molecular weight estimates of the B protein obtained by SDS–gel electrophoresis are mostly greater than this (see review, ref. 4), but the electrophoretic mobility varied with gel concentration and cross linker. Such anomalous behaviour suggests that there may be, for instance, carbohydrate attached to the B protein.

The C protein

The next known gene product, protein C, maps between genes *B* and *D*. Examination of the DNA sequence in this region indicates that the most probable initiating ATG overlaps the termination codon, TGA, of gene A in the sequence ATGA at position 134. A possible termination codon for gene *C* could then be at position 391, although the sequence and phasing is not yet confirmed through this region. There is another possible protein initiation codon (position 51, overlapping the B protein termination codon) which would result in a slightly shorter gene product terminating at nucleotide 219. For the C protein, however, we favour the 'A terminator' start, since only this reading frame contains a CAA sequence, which by a C→T alteration could give the ochre 6 mutant. Ochre 6 is a gene *C* mutant produced by the decay of ^{3}H-cytosine[51] and has been mapped in fragments A6 and F9 (ref. 52); that is, between nucleotides 170 and 205 (Fig. 1).

Sequence following the *D* promoter

The mRNA 5′ sequence which maps before the *D* gene (GAUGC)[34] is found at position 358 in Fig. 1. The sequence preceding the messenger start has only four of the TATPuATPu nucleotides[38]. Thirty-two nucleotides after the mRNA initiation is the ATG (position 390) that initiates D protein synthesis. The amino acid sequence of the D protein has been determined

16S RNA 3′ end	HO A-U-U-C-C-U-C-C-A-C-U-A-G	

Where the protein start has been independently confirmed by protein sequencing data the amino acid sequences are indicated. The other initiation regions were identified as described in the text. Sequences complementary to the 3′ end of 16S rRNA (refs 42, 43) are boxed; broken lines indicate further complementarity if some nucleotides are looped out or not matched. Ribosome binding to mRNA has been demonstrated in these regions for genes *J*, *F*, *G* and *B* (ref. 49).

almost completely, and nucleotide and amino acid sequences can be correlated to the termination codon at position 846 (ref. 33). The D protein, which is involved in capsid assembly, is 151 amino acids in length, with a molecular weight of 16,811. The *D* termination codon overlaps the initiation codon for gene *J* in the sequence TAATG. A similar structure has also been found by Platt and Yanofsky[53] in the tryptophan operon. The DNA sequence following this initiation codon matches the amino acid sequence of the small basic protein (37 amino acids) of the virion determined by D. Freymeyer, P. R. Shank, T. Vanaman, C.A.H. and M. H. Edgell (personal communication). Benbow *et al.*[8,9] suggested that the mutation *am*6 was located in a gene *J*, coding for the small protein of the virion, and mapping immediately before gene *F*. Although marker rescue experiments indicate that *am*6 is not in this region[54], the DNA sequence shows that there is a gene coding for the virion protein and we

Table 3 Promoter sequences in ΦX174

mRNA initiation sequences[44–46] are underlined. Boxed regions indicate sequences that may correspond to the TATPuATPu sequence found in other promoters[48], taking into account the distance from the mRNA starts.

have defined this as gene *J* (ref. 33). Since the *J* initiation codon overlaps the *D* termination codon we had to look elsewhere for gene *E*, which genetic mapping[2,3] had placed between them. Amber mutants in gene *E* (*am*3, *am*27, *am*34 and *am*N11) were located by the marker rescue technique and sequenced. All were found to be within the *D* coding sequence, with the mutant amber codons one nucleotide to the right of the *D* reading frame[33]. Thus the *E* coding sequence is completely contained within the *D* coding region but in a different reading frame. The proposed initiation and termination codons for the E protein are at nucleotides 568 and 840, respectively[33], giving a protein 91 amino acids in length with a molecular weight of about 9,900 (including the N-terminal methionine).

The F protein

Following the *J* gene is an intercistronic region of 39 nucleotides before initiation of the F protein. There is no known function of this apparently untranslated sequence, although the presence of a hairpin structure (positions 969–984) suggests that it could be the site of the *in vivo* messenger termination signal [37] mapped in this region. The F protein is initiated by the ATG at position 1,001. This is the capsid component of the virion, and almost all the amino acid sequence is known[33,34]. There are regions in this gene where the DNA sequence is not completely established, but the protein is about 424 amino acids in length, giving a molecular weight of ≃46,300.

The G protein region

The termination signal for the F protein (position 2,276) is followed by an unusually long untranslated sequence of 111 nucleotides until the G protein initiation codon[31]. This region contains a looped structure which was postulated to have some functional role, as yet unknown, in the single-stranded DNA or the mRNA.

Initiation of the G protein at position 2,387 is followed by a sequence of 425 nucleotides until termination at position 2,912, giving a spike protein of molecular weight 19,053. The nucleotide and amino acid sequences of this gene and product are known[34,35].

The H protein

The initiation codon for the H protein (position 2,923) was identified first on the basis of the distribution of T nucleotides between the three reading phases, and later confirmed by amino acid sequence analysis. Amino acid sequence data on the H protein is minimal but the five peptide sequences known do correspond to the amino acid sequence, deduced from the DNA sequence by using the high frequency of third position T to help in assigning a reading frame to any given region. The DNA sequence is not entirely confirmed but it is possible to write a reasonably accurate amino acid sequence for the H protein. The protein terminates at nucleotide 3,907, in agreement with carboxypeptidase results, giving a spike protein of molecular weight ≃ 35,600 (326 amino acids). The amino acid sequence at the N terminus seems to be particularly rich in hydrophobic residues, which is consistent with its suggested function as the 'pilot' protein that reacts with the bacterial membrane[45,46]. After H protein termination there are 66 nucleotides before initiation of the A protein at position 3,973.

Coding capacity of the ΦX174 genome

The most striking feature of the ΦX DNA sequence is the way in which the various functions of the genome are compressed within the 5,375 nucleotides. Since the identification of ΦX gene products[3,4] it has been clear that proteins of the accepted molecular weights could not be separately coded on the available length of DNA. However, with the presence of two pairs of overlapping genes (*B* within *A* (ref. 50), *E* within *D* (ref. 33)) the genome has more coding capacity than had been originally supposed on the assumption that each gene was physically separate. Table 1 summarises the molecular weights of the known ΦX-coded proteins. There are other potential initiation sites for polypeptide synthesis (for example, in genes *A*, *F*, *G* and *H*) and further genetic work may clarify whether there are in fact other ΦX genes as yet unidentified.

Initiation of protein synthesis

Table 2 lists the protein initiation sequences for genes *A*, *B*, *D*, *E*, *J*, *F*, *G* and *H*. It can be noted that there are no extra precursor sequences in proteins D, J, F, G or H at either the N or C terminus. There seems to be no relationship between the degree of complementarity to the 16S rRNA and the amount of protein synthesised, and we see no other features in the sequence that could explain different efficiencies of translation except where genes overlap.

Transcription of ΦX174

The sequences preceding known mRNA starts[54–56] are shown in Table 3. Other studies on promoter sequences[58] have suggested certain features that they may have in common. Although some of these features are present in the sequences preceding the ΦX transcription initiations others are not, and at present it is difficult to suggest what signal on the DNA determines a promoter site or the efficiency with which it initiates RNA synthesis. It is interesting to note that a polymerase binding site found by Chen *et al.*[57], but not associated with any *in vitro* or *in vivo* mRNA starts, mapped near the region where there is the sequence TATGATG characteristic of promoters[58] (positions 2,705–2,711).

Table 4 Codons used in ΦX174

Phe	TTT	39	Ser	TCT	35	Tyr	TAT	36	Cys	TGT	12
	TTC	26		TCC	9		TAC	15		TGC	10
Leu	TTA	19		TCA	16	Ter	TAA	3	Ter	TGA	5

	GTA	10		GCA	12	Glu	GAA	27		GGA	13
	GTG	11		GCG	12		GAG	34		GGG	3

The totals are derived from sequences in Fig. 1 which are fully confirmed, that is, 377 codons in gene *A*, 120 in gene *B*, 152 in gene *D*, 91 in gene *E*, 38 in gene *J*, 344 in gene *F*, 175 in gene *G* and 49 in gene *H*. Out of a total of 1,346 codons 42.9% terminate in T. The percentages in the different genes are: *A*, 37.1 (non-overlapping region 47.1; overlapping region 15.8); *B*, 34.2; *D*, 42.1; *E*, 14.3; *J*, 47.4; *F*, 52.0; *G*, 54.3; *H*, 49.0. The initiating ATG is included in all cases.

The use of codons in ΦX174

Table 4 shows the codons used in regions where the nucleotide sequence is fully confirmed. It is clear that the pattern established by early observations on non-random use of codons[23,24] is continued now that more information is available. In particular, the preference for T at the third position of the codon is marked throughout the genome, as shown in Table 4. In regions of overlapping genes, one of the pair tends to continue the 'third T' trend (*D* and *B*), thus excluding the other (*E* and *A*). This may give some indication of the order in which overlapping genes evolved[23,24]. Another interesting feature is the very low occurrence of codons starting AG, particularly in non-overlapping regions. The base composition of the sequence of ΦX174 DNA shown in Fig. 1 is: *A*, 23,9%; *C*, 21.5%; *G*, 23.3% and *T*, 31.2%. This is in good agreement with previously determined values (see ref. 4).

We thank D. McCallum and R. Staden for carrying out the computer data storage and analysis of the sequence.

Note added in proof: J. E. Sims and D. Dressler (personal communication) have independently determined the sequence in positions 263–375 and 4,801–4,940. Their results agree with those given in Fig. 1. They have also identified the 'B' mRNA start as being at position 4,888.

DNA sequence of a region of the ΦX174 genome coding for a ribosome binding site

Nigel L. Brown* & Michael Smith†

MRC Laboratory of Molecular Biology, Hills Road, Cambridge CB2 2QH, UK

The DNA region corresponding to a newly identified ribosome binding site in ΦX174 DNA is sequenced and mapped in relation to the physical map of ΦX174. Assignments of the binding site to a specific gene are discussed, and the possibility of a second case of overlapping genes in ΦX174 is considered.

RECENT studies on the DNA of bacteriophage ΦX174 have defined sequences corresponding to the ribosome binding sites of genes *D*, *J*, *F* and *G* (refs 1–3 and B. G. Barrell, personal communication). A ribosome binding site that does not correspond to any of the above sequences has now been defined by studies on a ribosome-protected fragment of a transcript *in vitro* of ΦX174 RF DNA (ref. 4). Inspection of preliminary DNA sequence data obtained from ΦX174 (F. Sanger, *et al.*, unpublished) for potential ribosome binding sites, and comparison of the sequence data with T_1-oligonucleotides from the unassigned RNA fragment[4], allowed identification of the DNA sequence corresponding to this RNA fragment. We report here the complete DNA sequence of a region of ΦX174 *am*3 RF DNA that corresponds to this new ribosome binding site. Because the DNA sequence contains accurately mapped cleavage sites for restriction endonucleases, the ribosome binding site can be located precisely on the physical map of the ΦX genome[5], and therefore located on the genetic map[6–8].

Determination of the DNA sequence

The ribosome binding site lies in that portion of *Hin*dII fragment 5 that overlaps *Hin*fI fragment 5a (nucleotides 5,000–5,100 approx, Fig. 1). The DNA sequence of this region was determined using the 'plus–minus' technique of Sanger and Coulson[9] (Fig. 2). It was quantitatively confirmed by characterisation of the pyrimidine oligonucleotides obtained by primed synthesis *in vitro* of DNA labelled with α-^{32}P-dATP or α-^{32}P-dGTP using viral or complementary strand as template[10,11] (Fig. 3, Table 1).

The sequence between the *Hin*dII 8/5 cleavage site and the *Hin*fI 5a/6 cleavage site contains 111 nucleotides. It also contains the *Alu*I cleavage sites between fragments 12b, 15b, 17 and 12a (Fig. 1). The sequence determination allowed the

Fig. 1 Restriction endonuclease fragment map of ΦX174 *am*3 RFI DNA. The origin of this map is the *Pst*I cleavage site, the scale being the number of nucleotides from that site. The direction of translation is from left to right. The boundaries of genes *A*, *B* and *C* are not precisely defined. The sequence described in this paper is 111 nucleotides between positions, 5,000 and 5,110 approximately. The data on which the cleavage map is based come from the work of Lee and Sinsheimer[23] (*Hae*III and *Hin*dII), Vereijken *et al.*[12] (*Alu*I) and Jeppesen *et al.*[5] (*Hin*dII, *Alu*I and *Hin*fI) except that the correct ordering of *Alu*I fragments A12b, A15b, A17 and A12a results from this sequence determination.

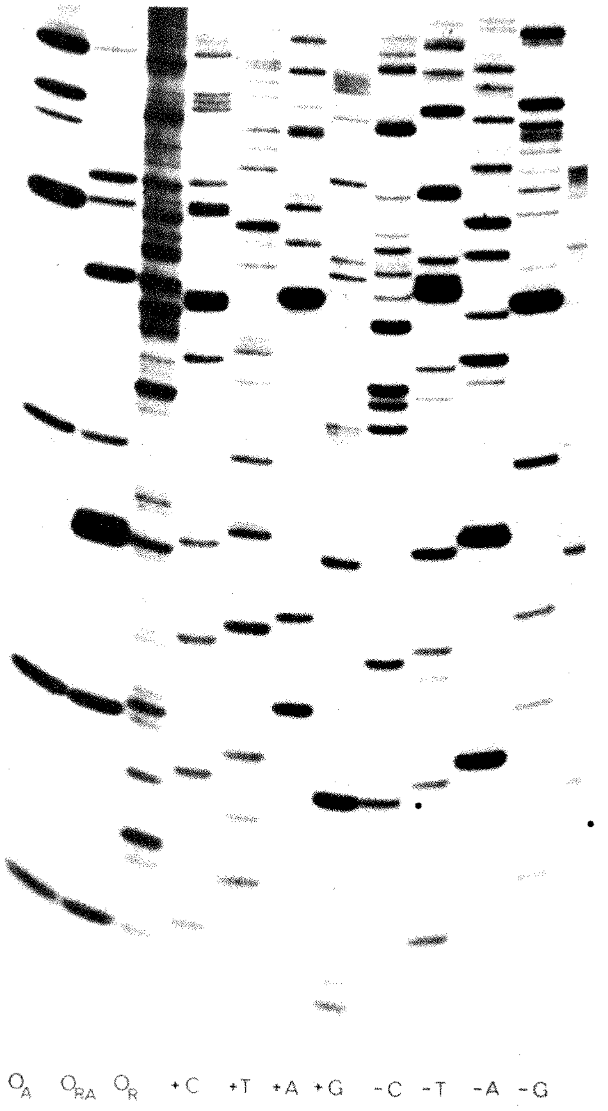

Fig. 2 The 'plus and minus' pattern produced by priming with *Hin*dII fragment R8 on complementary DNA template. This defines the sequence from nucleotide 19 to 88 (Fig. 4). The method used to locate the *Alu*I cleavage sites is that previously described for *Pst*I (ref. 24), except in that conditions were selected such that partial cleavage was obtained with *Alu*I. This allows location of all the *Alu*I sites in this region. The *Alu*I cleavage sites are defined by the two channels to the left of the plus and minus pattern, as bands which appear in channel O_{RA} but not in channel O_A.

correct ordering of *Alu*I fragments 12b, 15b, 17 and 12a for the first time[5,12]. The *Alu*I cleavage sites were mapped in relation to the plus–minus sequence determination as described in Fig. 2.

The sequence of the duplex DNA together with details of the determination is shown in Fig. 4.

Possible assignment of the ribosome binding site

As ΦX174 mRNAs are in the same sense as the viral strand[13], and the sequence corresponding to the RNA fragment protected *in vitro* is in the viral strand (nucleotides 33–69), this fragment could represent an *in vivo* ribosome binding site. The sequence implicated in ribosome binding (nucleotides 42–46) is in the expected relationship to an initiation codon (ATG, nucleotides 54–56)[14]. The adjacent DNA sequence allows the prediction of the sequence of the N-terminal 21 amino acids of the presumed protein product.

It is not possible unequivocally to assign this ribosome binding site, and the putative protein, to a particular gene. The limits of genes *H* and *D* are known in relation to the physical map of ΦX174 (ref. 1 and G. M. Air, A. R. Coulson F. Sanger, personal communication). The region between genes *H* and *D* contains genes *A*, *B* and *C*. In addition, a

Only the depurination products predicted from the gel sequence data were observed, and in their predicted molar yields. It was not possible to quantitate the products present in greater than three molar yield, and the predicted yields for these are given in parentheses.

*This depurination product established the identity of nucleotide 97 (A, Fig. 4) which was not identified by gel sequence data.

smaller protein (the A* protein) is produced by an internal translational start within gene *A* (ref. 15). The genetic evidence[7,16] and the size of the A protein[19] place the start of gene *A* close to the end of gene *H*. The size of the A* protein[17] and the genetic data[16] would allow its start in the general region of the new ribosome binding site. This assignment is, however, excluded by the termination codons, TAA, at nucleotides 3, 33 and 48 immediately in front of, and in phase with, the ATG at nucleotide 54.

Gene *C* maps a considerable distance to the right of the new ribosome binding site[7] and can therefore be excluded from consideration. The estimates of the size of the gene *B* protein[18–20] are compatible with the assignment of the site to gene *B*. The genetic data[7] places the start of gene *B* to the right of this site, within *Alu*I fragment 5. However, mutants in this region assigned to genes *A* or *B* behave aberrantly in reversion studies (C. A. Hutchison, personal communication) and the genetic data cannot therefore exclude the assignment of the site to gene *B*. A class of mutants, exemplified by *to*8, has been mapped within *Alu*I fragment 12a, and has therefore been assigned to gene *A* (ref. 21). This class may define a new cistron[21], however, and the ribosome binding site is compatible with such a cistron. An alternative possibility is that these mutants should be assigned to gene *B*.

In addition to the termination signals in the same phase as the initiation codon at nucleotide 54, this region of DNA contains two termination codons at nucleotides 41 (TAG) and 68 (TAA). Both of these are in a second phase. There are no termination signals in this region in the third phase. Therefore, the possibility of two overlapping genes, analogous to genes *D* and *E* (ref. 1), cannot be excluded. Such an overlap may help overcome the problem of fitting genes *A*, *B* and *C* (whose sizes[1] are calculated from the estimated molecular weights of their gene products[17–20,22]) into the available DNA, and may explain some of the paradoxes presented by the genetic data[7,21].

Determination of the N-terminal amino acid sequence of the B protein and any other likely gene products, and their comparison with the 21 amino acid sequence predicted from the DNA sequence data, should allow unequivocal assignment of this ribosome binding site. Further knowledge of the functions of this region of the genome will probably result from a more extensive DNA sequence determination on either side of the sequence presented here, and from examination of the DNA sequence in genetically defined mutants. The results of these studies are presented in ref. 25.

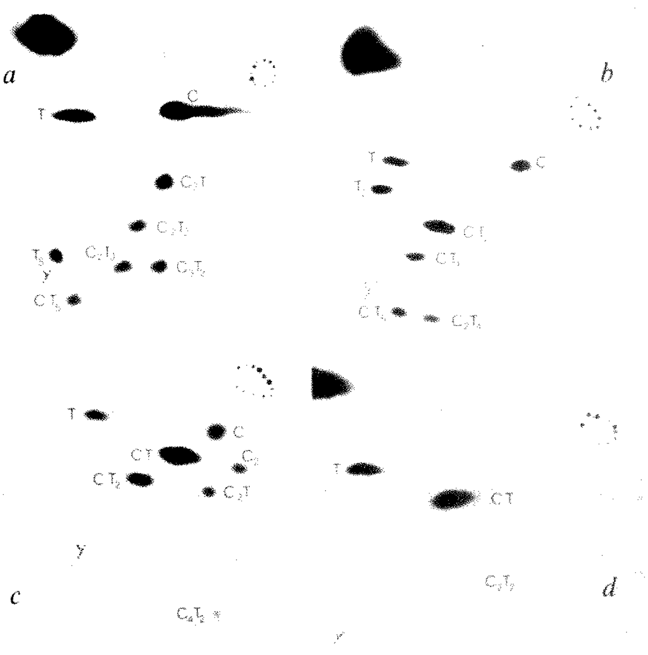

Fig. 3 Depurination analysis. The pyrimidine tracts in each strand were terminally labelled and isolated by the method of Fiddes[10]. *Hinf*I fragment 6 was used as a primer on viral strand DNA as template for primed synthesis with either α-^{32}P-dATP or α-^{32}P-dGTP label in separate experiments. *Hin*dII fragment 8 was similarly used as a primer on complementary strand DNA. The region between the *Hin*dII 8/5 and *Hinf*I 5a/6 cleavage sites was isolated by cleavage with both enzymes, followed by electrophoresis of the products on a gel containing 5% acrylamide, 2.5 mM EDTA, 90 mM Tris-borate (*p*H 8.3). The purified fragment was eluted in 0.5 M NaCl, 0.005 M EDTA, 0.1 M Tris-Cl (*p*H 8.5) and ethanol-precipitated. Depurination of the fragment and separation of the products were according to the methods of Ling[11]. As the products were end-labelled by nearest-neighbour transfer of ^{32}P from the adjacent purine, they could be quantitated by comparison of the relative intensities of the spots on the autoradiogram. The quantitative data is given in Table 1. *a*, *Hinf*I fragment 6, viral strand template, α-^{32}P-dATP label (that is, complementary strand depurination products). *b*, as (*a*), with α-^{32}P-dGTP label. *c*, *Hin*dII fragment 8, complementary strand template, α-^{32}P-dATP label (that is, viral strand depurination products). *d*, as (*c*), with α-^{32}P-dGTP label.

Fig. 4 The sequence of ΦX174 *am*3 RF DNA from the *Hin*dII 8/5 cleavage site to the *Hinf*I 5a/6 cleavage site. Plus and minus sequence determination priming with *Hinf*I fragment 6 on viral DNA template gave the sequence from 1 to 94. Priming with *Hin*dII fragment 8 on complementary DNA template gave the sequence 19–111. Thus most of the sequence is confirmed by complementary data, including the region corresponding to the ribosome protected RNA fragment (33–69; – – –). Nucleotide 97 (A) was established solely by depurination analysis. Termination codons are underlined, and restriction endonuclease cleavage sites are boxed. The presumed initiation codon is underlined with a wavy line. The sequence implicated in ribosome binding (AGGAG) is overlined.

Isolation and characterisation of the ΦX174 ribosome binding sites

Jeffrey V. Ravetch, Peter Model & Hugh D. Robertson

The Rockefeller University, New York, New York 10021

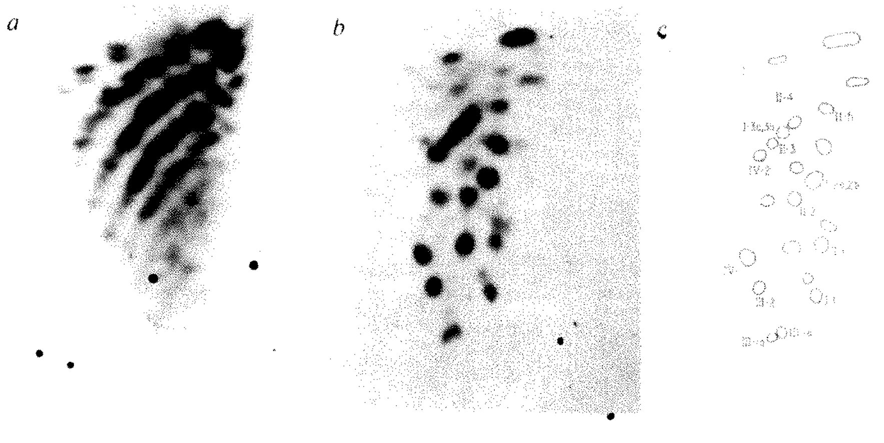
Sequence information for four RNA ribosome binding sites has been obtained from ΦX174 ΦRNA synthesised in vitro. *The ribosome binding sites have been assigned to sites on the ΦX174 genome by comparison with known DNA sequence data.*

ΦX174 is a single-stranded DNA bacteriophage with a genome of approximately 5,400 nucleotides which codes for nine products (for a review see ref. 1). In the infected cell the mRNA is transcribed from a double-stranded DNA replicative form and translated into the phage proteins. *In vivo*, the proteins made in largest amount are the products of genes *D*, *F* and *G* (refs 2 and 3). Robertson *et al.*[4-6] isolated a ΦX174 DNA fragment protected by ribosomes which contained a DNA sequence coding for the amino terminal portion of the gene *G* protein. In this laboratory, Pieczenik *et al.*[7] isolated and determined the sequences of three ribosome binding sites from the mRNA of bacteriophage f1 using techniques that have previously been shown to yield authentic protein initiation sites from the RNA bacteriophages[8-10].

We now have isolated and obtained sequence information for four RNA ribosome binding sites derived from ΦX174 mRNA synthesised *in vitro*. In an accompanying paper, Brown and Smith[11] report the DNA sequence of a ΦX174 region which includes one of these sites and thereby locates this site on the ΦX174 genome. Recently, Barrell *et al.*[12] have reported the DNA sequences encoding the amino termini of ΦX174 proteins D, J, F, G and H. Comparison of the DNA and the amino acid sequence data for these ΦX174 proteins allowed them to make these assignments.

Availability of these and other DNA sequence data[4-6,12] has allowed us to assign the other three ribosome binding sites to ΦX174 genes and to propose complete sequences for them. Our studies of the interaction of ΦX174 mRNA with ribosomes complement the DNA sequence data and allow us to define regions of the genome encoding signals for initiation of protein synthesis.

Fig. 1 Two-dimensional RNase T_1 fingerprint analysis of ΦX174 RNA transcripts before (*a*) and after (*b*) ribosome binding. *c*, Major oligonucleotides of the four ribosome binding sites (I, II, III and IV). Sequence analysis of these oligonucleotides is found in the text and Figs 3, 4 and 5. mRNA transcripts were prepared from ΦX174 RFI and in the experiment shown α-^{32}P-ATP at 130 Ci mmol^{-1} was used to prepare the material analysed here. Conditions of transcription and purification of transcripts are as described previously[21]. Ribosome binding was done as described by Steitz[9] and the fragments isolated and purified as described by Pieczenik *et al.*[7] Two-dimensional fingerprint analysis was carried out according to Barrell[22]. The origin is located in the lower right corner of the autoradiograph with electrophoresis at *p*H 3.5 on cellulose acetate proceeding from right to left and homochromatography from bottom to top on DEAE thin-layer plates.



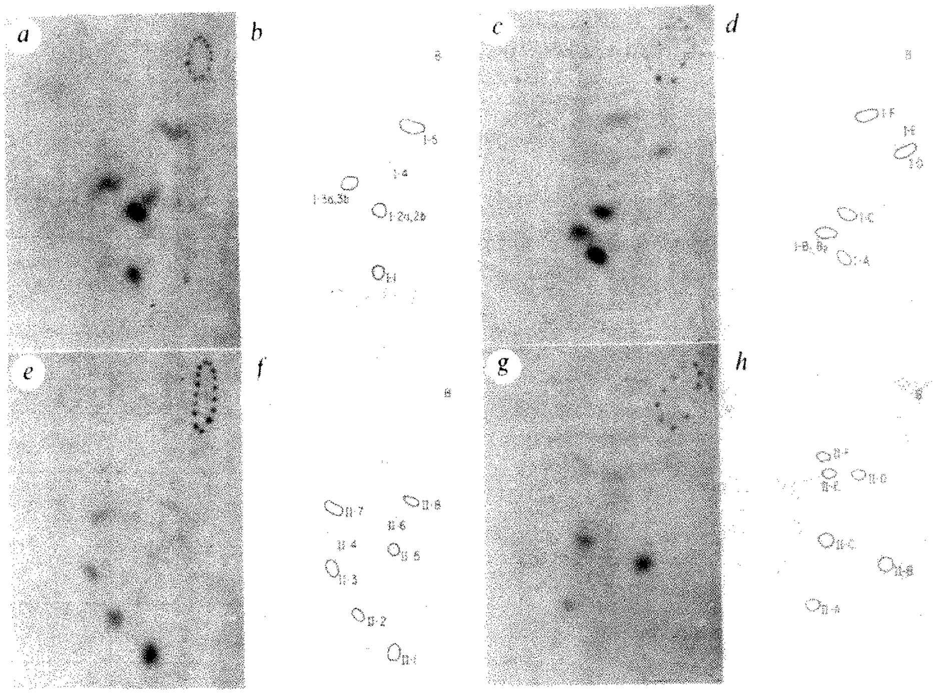


Fig. 2 RNase T_1 and pancreatic RNase fingerprinting analysis of the two ribosome binding site fragments purified by two-dimensional homochromatography. *a* (drawn in *b*) shows the RNase T_1 fingerprint of site I, while *c* (drawn in *d*) shows the pancreatic RNase fingerprint of site I. Site II is shown in *e–h* with the results of RNase T_1 digestion in *e* (drawn in *f*) and pancreatic RNase digestion in *g* (drawn in *h*). Sequence analysis of the oligonucleotides indicated here is discussed in the text and in Figs 3 and 4. Dotted circles represent spots not seen when α-^{32}P-ATP was used to synthesise mRNA, but found in analogous fingerprints of these sites using other α-^{32}P precursors. The origin is in the lower right-hand corner. B denotes blue dye mark. Details of the purification and fractionation of RNA ribosome binding site fragments using this approach are to be found in Pieczenik *et al.*[7]

Isolation of ribosome binding sites

ΦX174 RFI DNA was transcribed *in vitro* in the presence of α-^{32}P-nucleoside triphosphates to obtain labelled mRNA. Ribosomes were bound to these transcripts in conditions described previously[9] and the initiation complexes were digested with pancreatic RNase. Between 0.2 and 0.5% of the input mRNA was protected from RNase digestion and sedimented with 70S ribosomes in these conditions. Figure 1 shows two-dimensional RNase T_1 fingerprint analysis of ΦX174 mRNA (*a*) and its ribosome-protected fragments (*b*). Panel (*c*) identifies the major RNase T_1-resistant oligonucleotides (T_1-oligonucleotides) obtained from the unfractionated mixture of ribosome-protected fragments. Figure 1 shows that protection of ΦX174 mRNA by ribosomes results in a considerable simplification of the T_1-oligonucleotide pattern.

To obtain homogeneous ribosome-protected fragments for further sequence analysis, the mixture of fragments was fractionated using homochromatography as the second dimension of a two-dimensional system[13], yielding two purified ribosome binding site species (data not shown). Figure 2 shows RNase T_1 and pancreatic RNase fingerprinting analysis of ribosome binding site I (*a–d*) and ribosome binding site II (*e–h*). Experiments were carried out with mRNA labelled by each of the four α-^{32}P-ribonucleoside triphosphates individually, or labelled by all four triphosphates. Nearest neighbour sequence analysis was exploited to generate the sequence of each oligonucleotide, as well as to determine the order of several of the oligonucleotides[7].

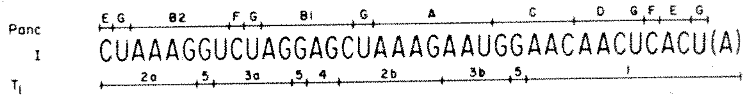

Fig. 3 Sequence analysis of ribosome binding site I. Conditions for base composition and nuclease digestion are according to Barrell[22]. NTP refers to the α-^{32}P-ribonucleoside triphosphate precursor used to synthesise the oligonucleotides analysed in a given line. N.D. means that the oligonucleotide in question was obtained but the analysis was not done, and a dash signifies that the particular oligonucleotide was not present. The sequence shown at the top of the table is the only arrangement of T_1 (shown by the number below the sequence) and panc oligonucleotides (shown by the letters above the sequence) consistent with the data shown here. *Nucleotides found to be labelled after base composition analysis. ‡RNase U_2 occasionally incomplete digestion products and yielded undigested starting material.

Fig. 4 Sequence analysis of ribosome binding site II. The ordering of T_1 oligonucleotides 1, 2 and 3 is dependent on the DNA sequencing data of Barrell *et al.*[12]. Other details are as in the legend to Fig. 3. †The data obtained do not specify the value of n beyond the fact that $n > 4$. The actual value of n is derived from the DNA sequence data of Barrell *et al.*[12].

Sequence analysis of binding site I

The nucleotide sequence of binding site I was determined. Figure 3 shows the T_1 and pancreatic RNase-resistant oligonucleotides (panc oligonucleotides) obtained from the purified species shown in Fig. 1 (*a–d*). T_1 oligonucleotides 2a and 2b were present as a mixture and could be distinguished by nearest neighbour labelling patterns. The mixture of T_1 oligonucleotides 3a and 3b was resolved into two components by electrophoresis on DEAE paper in 7% formic acid (data not shown). Panc oligonucleotides B_1 and B_2 were distinguished by their nearest neighbour labelling pattern. In binding site I, the panc oligonucleotides allow us to order the T_1 oligonucleotides yielding the sequences we have written.

The single base overlap of T_1 oligonucleotides 4 and 2b generated by panc oligonucleotide B_1 is unambiguous since T_1 oligonucleotide 4, AG, is uniquely labelled by a C nearest neighbour, a feature shared by no other T_1 oligonucleotide in Fig. 3. This establishes that AG must be located 5′ to a T_1 oligonucleotide whose 5′-end is C. T_1 oligonucleotide 2b, CUAAAG(A), has been overlapped with T_1 oligonucleotide 3b by panc oligonucleotide A and is the only candidate which can label AG by C. We can therefore write the sequence . . . AGC(U), a sequence that can only come from panc oligonucleotide B_1, establishing the sequence as we have written it.

Sequence analysis of other ribosome binding sites

The data substantiating the other purified ribosome binding site fragment shown in Fig. 2 (*e–h*), are summarised in Fig. 4. The sequence written relies upon the DNA sequence data obtained by Barrell *et al.*[12] to determine the value of n in T_1 oligonucleotide 1, $A_nCG(U)$ and to order the T_1 oligonucleotides 1, 2 and 3.

We have obtained and sequenced additional T_1 and panc oligonucleotides from the mixture of unfractionated ΦX174 ribosome binding sites (see Fig. 5). We were unable to purify the individual ribosome binding sites to which these could be assigned. Thus the overlaps shown in Fig. 5 were derived from a comparison of these oligonucleotide sequences with DNA sequence data[4–6,12].

The sequences of the four ΦX174 ribosome binding sites are shown in Fig. 6, with their predicted amino acid sequences as specified by the codons following the AUG.

The assignment of these RNA ribosome binding sites to ΦX174 genes has been possible as a result of the DNA sequence information accumulated for ΦX174 by Brown and Smith[11], Barrell *et al.*[12] and Robertson *et al.*[4–6]. Site I is believed to correspond to the initiation site for gene *B*, on the basis of the data of Brown and Smith[11], whose independent sequence analyses have assigned this sequence to restriction fragments mapping within gene *B*. Site II has been identified as the gene *J* initiation site on the strength of the DNA and protein sequence information obtained for that region of the genome (ref. 12 and B. G. Barrell, in preparation). Similarly, site III can be assigned to the gene *F* initiation site[12,14,15] and site IV has been identified as the gene *G* initiation site[4–6].

ΦX174 specifies nine viral gene products. As in the case of f1 (ref. 7), the *in vitro* ribosome protection method does not yield mRNA fragments corresponding to each potential protein initiation site. Rather, a subset of potential sites is protected from nuclease digestion. In addition, in the case of ΦX174 Robertson *et al.*[4–6] have shown that a single predominant species, derived from gene *G*, is protected from DNase digestion when ΦX174 single-stranded viral DNA is bound to ribosomes. We have found that site IV (gene *G*) is not consistently isolated as an RNA ribosome binding site and when present is seen in the lowest yield of the four sites described here. We have found no obvious correlation between the recovery of any specific ribosome binding site and the amount of the corresponding protein synthesised either *in vivo*[2,3] or *in vitro*[16].

Recently, Shine and Dalgarno[17] have proposed that the 3′-end of 16S rRNA, 5′-GAUCACCUCCUUA$_{OH}$, is able to form Watson–Crick base pairs with sequences within the RNA ribosome binding sites, stabilising protein initiation sites in ribosome–mRNA complexes. That such base pairs can, in fact, be formed was demonstrated directly by Steitz and Jakes[18]. It has been shown, however, that an intact 3′-end of 16S rRNA

is not required to form stable initiation complexes *in vitro*[10]. Indeed, in all ribosome binding sites sequenced to date, such potential complementarity to the 3′-end of 16S rRNA has been found to exist. The four ribosome binding sites reported here all possess sequences that have the potential to form base-paired complexes with the 3′-end of 16S rRNA. Thus, the sequence 5′ . . . AGGAG . . . 3′ present in site I has the potential to form five such base pairs, site II can form a possible ten base-paired complex (if a single base is looped out of the 3′-end of 16S rRNA), while sites III and IV can each form a possible five base pairs. The same base-pairing schemes for the DNA sequences encoding sites II, III and IV have been proposed by Barrell *et al.*[12], along with similar schemes for genes *D*, *E* and *H*. We can find no correlation between the number of potential Shine–Dalgarno base pairs seen in an initiation site and the efficiency of ribosome binding and protection *in vitro*. Clearly, other factors must determine which of the protein initiation sites are selected and recognised by ribosomes in our *in vitro* system.

Brown and Smith[11], in an accompanying paper present evidence that site I may be the gene *B* ribosome binding site. Their data suggest that the gene *B* protein is encoded by the DNA sequence which also codes for the carboxy-terminus of the gene *A* protein. Barrell *et al.*[12] have shown that gene *E* is similarly coded for by the DNA sequence which also codes for the gene *D* protein. We have found no evidence for a ribosome binding site *in vitro* for either gene *D* or gene *E*. Thus the transcripts from one of the 'included' genes are efficiently protected by ribosomes while those from the other are not.

Binding site II, the proposed gene *J* binding site, contains the sequence 5′-GGAAGGAG$\overline{\text{UGA}}$UG$\overline{\text{UAA}}$UG . . . 3′. The indicated UGA codon would terminate the proposed gene *E* protein[12], whereas the indicated *D* termination codon (UAA) overlaps the indicated gene *J* initiation codon (AUG) by a single base. Platt and Yanofsky[20] have observed a similar one-base overlap between the termination of one gene and the initiation of a second gene in the tryptophan operon. Here two termination signals and one functional initiation signal are compressed within ten bases showing that large intercistronic spaces are not required to separate signals for gene expression.

Homologies between published ribosome binding site sequences have been reported. Here we find that sites III (gene *F*) and IV (gene *G*) have a seven out of eight base homology to the left of and including the AUG. In addition, site IV (gene *G*) has six bases (UUUAAU) in common with f1 binding site 1 (gene *VIII*) (ref. 7) and nine out of ten bases from the same region in common with the Qβ coat protein ribosome binding site[10]. Further analysis will be required to assess the significance of these homologies.

Finally, it should be noted that site IV (gene *G*) is considerably smaller when protected as an mRNA species in a ribosome binding complex than when the single-stranded viral DNA is used in the *in vitro* binding system. Robertson *et al.*[4–6] sequenced a 49-nucleotide protected fragment. We find the fragment which is identified as the gene *G* ribosome binding site has a sequence of only 21 nucleotides. The 14 nucleotide-long

Fig. 6 Proposed sequences of the four RNA ribosome binding sites of ΦX174. Details of the sequence analysis are described in the text and Figs 3, 4 and 5. The nucleotide in parentheses at the 3′-end of each sequence represents the nearest neighbour nucleotide determined for the 3′-terminal RNase T_1 digestion product in each case. Binding site I predicts an amino terminal sequence for the gene *B* protein (see text and the accompanying paper). Binding sites II, III and IV specify the amino termini of genes *J*, *F* and *G* (refs 12 and 14–16).

T_1 oligonucleotide on the 3′-end of the DNA sequence was not recovered, nor was a seven nucleotide-long T_1 oligonucleotide on the 5′-end of the DNA sequence. Both of these T_1 oligonucleotides contain extensive polypyrimidine tracts which might explain the poor recovery of these oligonucleotides in the conditions of pancreatic RNase digestion used here to isolate ribosome protected fragments.

We have carefully compared the sequences of these four ribosome binding sites with the six potential ribosome binding sites described by Barrell *et al.*[12] but are as yet unable to explain why only four are recovered in this *in vitro* system. Those which are recovered allow us to define, in conjunction with the accompanying paper and earlier studies[4–6,11], additional functional regions of the ΦX174 DNA sequence.

We thank Bart Barrell, Nigel Brown and Mike Smith for generously providing DNA sequencing data in advance of publication. We further thank Bart Barrell for helpful suggestions, and George Pieczenik and Norton Zinder for encouragement, advice and suggestions. We thank Edward Pelle and Carolyn McGill for technical assistance. This research was supported in part by grants from the US NFS and the US National Institutes of Health.

Sequence determination of mutants in genes A *and* B *confirms that these constitute another pair of genes in ΦX174 which are translated from the same DNA sequence using different reading frames.*

BACTERIOPHAGE ΦX174 is known to code for nine proteins in its DNA (ref. 1) which is about 5,400 nucleotides in length (Fig. 1). The locations of the boundaries of six of the genes—*D*, *E*, *J*, *F*, *G* and *H*—have been defined by sequence determination (F.S. *et al*, in preparation). Two of these genes (*D* and *E*) overlap on the DNA sequence[1]. To define the boundaries for genes *A*, *B* and *C* which lie in the remaining region between gene *H* and gene *D*, the sequence of ΦX174 *am*3 DNA in the region between the *Hae*III 6a/6b and the *Taq*I 2/7 sites (Fig. 1) has been determined (N.L B. and M.S., in preparation). A newly recognised ribosome binding site[3] has been located in the sequence[4]. The sequence determination of a *B* gene mutant—*am*16—strongly suggested that the *A* and *B* genes are translated from the same DNA using different reading frames (N.L.B. and M.S., in preparation). We now report the 200 nucleotide sequence of ΦX174 *am*3 DNA from the *Taq* 2/7 to the *Hha* 8b/4 sites (Fig. 1). In addition, the sequences of three mutants from this region—*am*18 and *am*35 (gene *A*) and a revertant of *am*18, *ts*116 (gene *B*)—have been determined. The mutants *am*18 and *am*35 have an

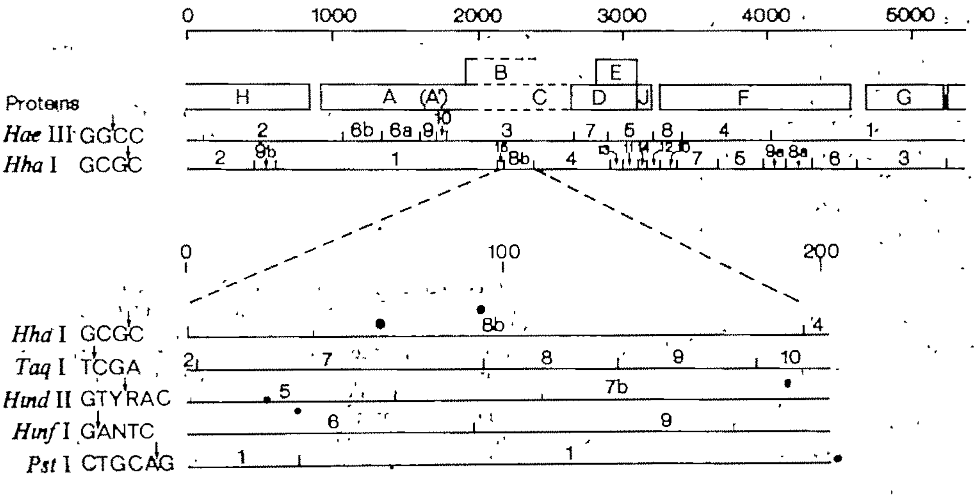

Fig. 1 Map of the ΦX174 genome showing the *Hae*III and *Hha*I fragments and the protein-coding sequences and details of other restriction cleavages within *Hha* fragment 8b.

amber codon at the same site. The gene *B* mutant, *ts*116, results from a single base change in the termination codon of *am*18/35. These results confirm the overlap of genes *A* and *B* and establish the C-termini of the two genes.

Nucleotide sequence analysis

The cleavage sites of five restriction enzymes which cleave in the region are shown in Fig. 1. The sequence of the DNA was obtained by a slight modification of the 'plus and minus' method (ref. 5 and N.L.B. and M.S., in preparation) by priming from the *Hin*fI 6/9 site, on both viral and complementary templates and from the *Pst*I site on the complementary template (Fig. 2). The sequence was confirmed by depurination analysis[6] of *Taq*I fragments 7, 8, 9 and 10 labelled by 'nick translation'[7] of ΦX174 *am*3 RFI DNA.

Nucleotide sequence of *A* and *B* mutants

Gene *A* mutants (*am*18, *am*35) have been mapped[8] between the left end of *Hha*I fragment 8b (fragment 7b in ref. 8) and the right end of *Hin*dII fragment 5. The mutant *am*18 and its revertant *ts*116 do not recombine to product *wt* progeny at a frequency above background. These experiments set an upper limit of approximately three nucleotides on the distance separating these mutants[9]. The *B* gene mutant (*ts*116) maps close to, or in, the *Hin*dII 5/7b site[10]. Consequently, the mutant sequences can be determined very easily using the plus and minus method by priming from the *Hin*fI 6/9 site on the mutant viral strand template. The results of these determinations for *am*3 (*E* gene mutant; wild type in this region), *am*18, *am*35 and *ts*116 are shown in Fig. 3. The independently isolated *A* gene mutants, *am*18 and *am*35, show the same altered nucleotide sequence. In the viral strand, this is a C → T transition at nucleotide 64 (Fig. 2) which results in a CAG → TAG change producing an amber codon in the reading frame which has been assigned to gene *A* (N.L.B. and M.S., in preparation). No other alterations in the *am*18 or *am*35 sequences can be seen between the *Hin*dII 5/7b site and the *Pst*I site (Fig. 2). This transition also results in an amino acid change (Ala→Val) in the reading frame assigned to gene *B* on the basis of the phasing of the ribosome binding site[3,4] and the gene *B* mutant, *am*16. This assignment of the *am*18, *am*35 (gene *A*) mutation to a specific site to the right of the *am*16 (gene *B*) as originally suggested by recombination mapping[1,9,11], and to a different reading frame, verifies the overlap of genes *A* and *B*.

The gene *B* mutant, *ts*116, was isolated as a revertant of *am*18. The mutation is a G → C change at nucleotide 66, which produces a TAG→TAC (amber→Tyr) codon change in the gene *A* reading frame. In gene *B*, the mutation results in a GAA→CAA (Glu→Gln) codon change. The resultant change in charge may be responsible for the *ts* phenotype.

The original stocks of these *am* mutants were obtained after nitrous acid treatment of viral DNA. The mutations characterised so far include G → A (*am*3,34; *am*N11,27) (ref. 2), C → T (*am*18,35) and G → T (*am*16). This variety of mutations illustrates the caution which should be exercised in predicting the consequences of chemical mutagenesis[12].

Fig. 2 Summary of the plus and minus sequence determination of the *Hha*I fragment 8b region. At the left of each determination is indicated the fragment used as the origin of the plus and minus priming. (The single letter designations used for restriction endonucleases are: *Taq* I (T), *Hin*fI, (F); and *Pst*I, (P)) Fragments indicated in parentheses are the primers used when these differed from the one corresponding to the origin (for example, F9(T8) indicates that T8 was the primer with the origin at the adjacent *Hin*fI site). The letters V and C indicate that the template was viral or complementary strand DNA, respectively. The designations (S) or (L) indicate the use of a short (4 h) or long (8 h) gel electrophoresis run.

Fig. 4 The sequence of ΦX174 viral DNA in the region of gene *B* and the C terminus of gene *A*. The amino acid sequences of the gene *A* and gene *B* proteins predicted from the DNA sequence are shown together with the changes resulting from the mutations *am*18 and the subsequent *ts*116, *am*35 and *am*6.

The changes induced in the second gene by mutation in its overlapping companion are not necessarily restrictive, as evidenced by the Leu→Phe change in gene *A* which accompanies the *am*16 mutation in gene *B*, the Ala→Val change in gene *B* accompanying the *am*18,35 mutation in gene *A*, and the reversion of *am*18, which by two steps induces a Gln → Tyr in gene *A*. There is no evidence for any impairment in protein function due to these changes, whereas in *ts*116 the second amino acid change (Glu→Gln) in gene *B* which follows the initial change (Ala → Val) induced by the gene *A* amber mutation evinced a phenotypic response (*ts*).

C termini of A and B proteins

The sequence determination and establishment of the *A* gene reading frame taken together with the *B* gene reading frame allow the prediction of the C termini of the two proteins (Fig. 4). The B protein is 120 amino acids long with a molecular weight of 13,845. The *A* gene extends for 85 nucleotides (28 codons) beyond the C terminus of gene *B*. If, as has been suggested (N.L.B. and M.S., in preparation), the gene *A*/gene *B* overlap arose by read-through of a previously shorter gene *A*, then a question arises about the original role of the DNA beyond the C terminus of gene *B*. The mutant *am*6 is a double amber mutant mapping in fragments F9 (gene *A*) and Z7 (gene *E*) (P. Weisbeek, personal communication). In gene *E* the mutation is identical to *am*3. The gene *A* mutation has also been sequenced and is a G → A change at nucleotide 158. This gives an amber (TAG) codon, and would result in a gene *A* product six amino acids shorter than in the wild type. In addition there is a C → T change at nucleotide 98 which would result in a missense Ser → Leu in the gene *A* protein, and preliminary results suggest yet another change in this region. The resulting gene product is impaired in function, indicating that there is some requirement for the region of the A protein coded by the DNA beyond the end of gene *B*.

We thank R. Kamen, R. J. Roberts and S. Sato for gifts of some of the enzymes used in this study. The *am*18 and *am*35 stock were kindly provided by H. S. Jansz.

Photochemical attachment of cyclic AMP binding protein(s) to the nuclear genome

John Kallos*

Department of Biochemistry, College of Medicine and Dentistry of New Jersey, New Jersey Medical School, Newark, New Jersey 07103

The nature of the cyclic AMP–receptor–nucleus interactions was examined by a novel combination of two photoreactions. A photosensitive derivative of cyclic AMP, N^6-butyryl cyclic AMP, was covalently attached to its cytoplasmic receptod by photo-affinity labelling and this receptor complex was photo-crosslinked by the DNA in the rat liver nuclei. The photolytic reactions seemed to be specific since stable links were formed only when substantial noncovalent binding occurred.

CLOSE similarity between two modes of signalling to the nucleus in mammalian cell regulation, one by steroid hormones[1–5] and the other by cyclic nucleotides[6–10], has been suggested. Both steroid hormones and cyclic AMP combine specifically with a cytoplasmic receptor protein, and then the resulting ligand–receptor complex enters into the nucleus, where it binds to the genome. Little is known of the nature of these hormone–receptor–genome interactions. A requirement for the solution of this problem is the identification of the residues involved in the protein–DNA interactions in the nucleus.

I intend to study the chemistry of the ligand–receptor and receptor–genome interactions and to freeze the *in situ* interacting residues by the covalent attachment of the ligand to the receptor and the receptor complex to the genome in the intact nucleus, so that these residues can be identified. I report here the combined use of two well-known photolabelling techniques. In one, photo-affinity labelling[11–13], the ligand derivative is covalently attached to the receptor protein to identify the ligand binding site. In the other, the photo-induced crosslinking reaction[11,14–18], the protein and nucleic acid are linked together to locate the segments of the macromolecules that are in close contact. This method of 'photo-affinity crosslinking' is based on the ability of the mobile cytoplasmic receptor to bind its ligand specifically and then to migrate to the nuclear site, thus delivering a photosensitive probe to form a ternary nuclear complex.

Photo-affinity crosslinking was used to study the covalent attachment of cyclic AMP to its 'receptor' and the crosslinking of the receptor complex to DNA in the intact nucleus. (In this paper the term 'receptor' is used to signify a high affinity cyclic AMP binding site.) The previously described cyclic-AMP–receptor–nucleus *in vitro* system from rat liver was used[19]. The N^6-butyryl derivative of cyclic AMP (NBcAMP)[20–21] was chosen for photo-affinity labelling because the carbonyl group on the acyl side chain can be electronically excited by irradiation to a chemically reactive species[22]. This excitation can produce a variety of free radicals from the rupture of the bond in the α position to the carbonyl (α cleavage) or a 1,5 hydrogen shift of the γ-hydrogen (hydrogen abstraction) and leads to the covalent bond formation between the ligand and the receptor[11,22].

Preliminary photo-affinity labelling studies of the cytoplasmic receptor with NBcAMP encouraged us to explore the applicability of receptor site labelling in a more complex system, the cell nucleus. It was expected that NBcAMP would bind specifically to its cytoplasmic receptor proteins,

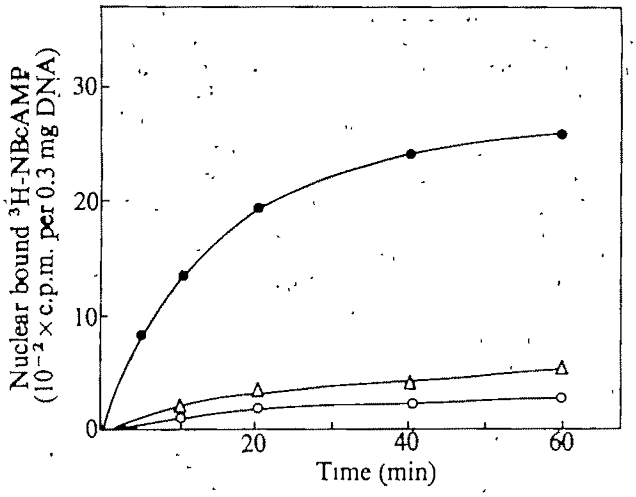

Fig. 1 Time course, temperature dependence and cytosol requirement for the specific uptake of ^{3}H-NBcAMP by isolated rat liver nuclei. Purified liver nuclei were prepared as before[19]. Nuclei (0.30 mg of DNA) were suspended in 0.5 ml of buffer A (0.30 M sucrose, 25 mM KCl, 2 mM $CaCl_2$, 1 mM $MgCl_2$, 3 mM mercaptoethanol, 50 mM Tris-HCl, *p*H 7.5) and incubated at 4 °C or 25 °C for the indicated times with 0.35 ml of liver cytosol[10] (~15 mg of protein, ml^{-1}, 105,000*g* supernatant fraction and equilibrated with buffer B (25 mM KCl, 3 mM mercaptoethanol, 1 mM EDTA, 15% glycerol, 50 mM Tris-HCl, *p*H 7.5) either by gel filtration through Sephadex G-25 or by dialysis) in the presence of 1×10^{-7} M ^{3}H-NBcAMP (New England Nuclear) Following incubation, the mixture was chilled, diluted with 2.5 ml cold buffer A, centrifuged (900*g*. 8 min) and the pellet washed three times with 4 ml of buffer A and finally the nuclear pellet was solubilised (in 0.5 ml of 0.20 M NaOH containing 0.025% SDS) Aliquots were assayed for radioactivity (by liquid scintillation counter) and for DNA (by A_{260}) Each value represents the average of 6 determinations The specific binding of ^{3}H-NBcAMP was calculated from the difference in the assay performed in the presence or absence of 500-fold excess of nonradioactive NBcAMP. ●, Incubation at 25 °C with cytosol; △, 25 °C, no cytosol; ○, 4 °C with cytosol.

that this complex, on activation, should migrate into the nucleus to form a nuclear complex, and that photolysis of this nuclear complex should ultimately result in covalent attachment of cyclic AMP derivatives to its receptor and in photochemical crosslinking of the receptor to nuclear DNA. The validity of these predictions was tested.

Nuclear binding of NBcAMP–receptor complex

There is a cytosol requirement for the *in vitro* transfer of cyclic AMP from cytoplasm to nucleus[19]. Here I demonstrate, in a similar system, the reversible binding of the NBcAMP–receptor complex to the purified nuclei. When rat liver nuclei were incubated at 25 °C with ^{3}H NBcAMP in the presence of cytosol, there was time dependent binding of the radioactivity to the nucleus (Fig 1). In the absence of cytosol, ^{3}H-NBcAMP bound poorly to the nuclei Neither heat denatured cytosol, bovine serum albumin (BSA) alone, nor trypsin treated cytosol could stimulate the transfer of ^{3}H-NBcAMP (Table 1), suggesting that the entire cytoplasmic receptor complex, and not the cyclic nucleotide alone, was transferred to the nucleus

I have shown that nuclear binding of cyclic AMP, in close similarity to the steroid systems, requires a time, temperature and ligand dependent transformation of the receptor complex, resulting in its increased affinity for the chromatin or for DNA. This was termed the 'activation' step. A similar time and temperature dependence was demonstrated for NBcAMP–receptor complex (Fig. 1). At 25 °C, the transfer was nearly complete in 30 min, but at 4 °C the reaction was much slower.

The binding of ^{3}H-NBcAMP to cytosol receptor seems to be specific since the interaction could be prevented only by the addition of a large excess (400-fold) of nonradioactive cyclic AMP or NBcAMP, but not by excess of ATP, AMP, or GMP (Table 1) The fact that the NBcAMP binding was inhibited by cyclic AMP as well as by NBcAMP suggests that they both interacted with the same receptor site[19,21].

The nuclear binding of the receptor complex seems to be noncovalent, since the NBcAMP–receptor complex is extractable from the nucleus with 0.4 M KCl In addition, there is no apparent chemical change in the cyclic nucleotide during the nuclear binding, since at least 90% of the bound radioactivity was shown to be identical with ^{3}H-NBcAMP on TLC[19,22].

Photolytic incorporation of NBcAMP–complex into the nucleus

Preliminary photo-affinity labelling studies of the cytoplasmic receptor with ^{3}H-NBcAMP (in preparation) en-

Table 1 Cytosol requirement and comparison of non-covalent and covalent nuclear binding of ^{3}H-NBcAMP

Nuclei (0.7 mg of DNA) and cytosol (0.75 ml; 12–15 mg protein per ml) were incubated with 1×10^{-7} M ^{3}H-NBcAMP for 50 min at 25 °C. After the samples were chilled, centrifuged and washed, the nuclear bound ^{3}H-NBcAMP was determined as described in Fig. 1.

*Photolysis of the ^{3}H-NBcAMP nuclear complex (prepared as above) was carried out as described in Fig. 2 for 15 min; aliquots were assayed by TCA precipitable radioactivity.

†Cytosol was treated with trypsin (0.2 mg ml^{-1}, Worthington) for 30 min at 25 °C and then soybean trypsin inhibitor (0.35 mg ml^{-1}) was added for 5 min before incubation with the nuclei.

‡Photolysis of ^{3}H-NBcAMP ternary nuclear complex was carried out as described in Fig. 2*b*, followed by enzymatic digestion with DNase (0.1 mg ml^{-1}), RNase (0.1 mg ml^{-1}) and trypsin for 45 min at 30 °C as described in Fig 3 and finally analysed for TCA insoluble radioactivity as above.

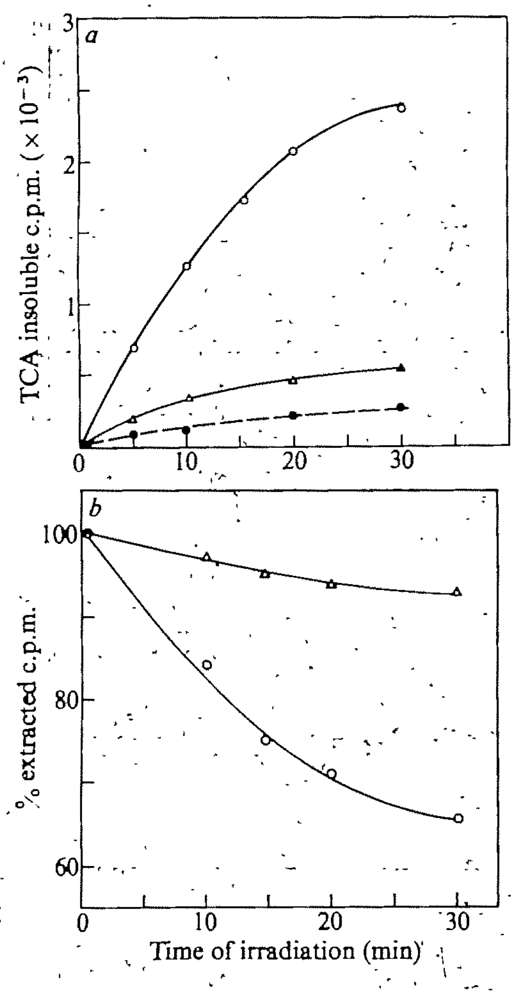

Fig. 2 Time dependence of the photolytic incorporation of ^{3}H-NBcAMP into the nuclear complex. *a*, TCA precipitable counts; the ^{3}H-NBcAMP nuclear complex was prepared, as described in Fig. 1, by incubating nuclei (1 mg of DNA) and cytosol (1.2 ml, 12–15 mg of protein ml^{-1}) at 25 °C for 50 min with ^{3}H-NBcAMP (1×10^{-7} M) and resuspended in 2.5 ml of buffer C (0.20 M sucrose, 25 mM KCl, 2 mM $CaCl_2$, 1 mM $MgCl_2$, 7.5 mM mercaptoethanol, 1 mM EDTA, 20% glycerol, 50 mM Tris-HCl, *p*H 7.5) and placed into wells of a plastic culture plate on ice, equipped with magnetic stirrer. The reaction mixture was irradiated at a distance about 8 cm with a 25-W mercury lamp (General Electric, predominantly 253.7 nm radiation). At the indicated time, 0.60-ml aliquots of the irradiated mixture were assayed by TCA precipitable radioactivity (2 ml of cold 20% TCA was added to the aliquots, centrifuged, and washed 3 times with 4 ml of 5% TCA), the pellet was dissolved in 0.5 ml of 0.20 M NaOH containing 0.025% SDS and assayed for radioactivity. ^{3}H-NBcAMP–cytoplasmic receptor complex was prepared by incubating cytosol (3 ml) with ^{3}H-NBcAMP (1×10^{-7} M) for 30 min at 4 °C and equilibrated with buffer B either gel filtration (through Sephadex G-25) or by dialysis, and finally was irradiated as above. Controls were treated identically, but were not exposed to ultraviolet light. Complete nuclear incubation mixture irradiated (○); complete nuclear mixture unirradiated (control) (●); irradiated in the absence of cytosol (Δ). *b*, Percentage of radioactivity released by 0.4 M KCl versus time of irradiation; photolysis of ^{3}H-NBcAMP nuclear complex was performed in the absence and presence of 0.4 M KCl in buffer C as described above. At indicated times aliquots were removed, KCl concentration uniformly adjusted to 0.4 M, centrifuged, extracted again with 1 ml of 0.4 M KCl (in 50 mM Tris, *p*H 7.5), and the combined supernatant (nuclear extract) was assayed for the protein bound radioactivity by gel filtration (13 × 1.25-cm column of Sephadex G-25); 65–75% of the extracted nuclear radioactivity was present in the macromolecular fraction. The amount of released radioactivity from the nuclei is expressed as a percentage of the nonirradiated control. Irradiation in the absence (○) and in the presence (Δ) of 0.4 M KCl.

Table 2 Activation and photochemical fixation

	Salt extracted (c.p.m.) from nuclei (% of control)
Activation at 25 °C (control; no ultraviolet)	100
Activation followed by ultraviolet*	69
Ultraviolet exposure followed by activation†	93
Activation followed by ultraviolet and then the DNase digestion‡	98

Nuclear suspension (0.35 mg DNA) and cytosol (in the same ratio as in Fig. 1*a*) were incubated in buffer C with 1×10^{-7} M ^{3}H-NBcAMP for 50 min at 25 °C, then incubated again for 20 min at 4 °C (in the irradiation plate, as in Fig. 2, but not exposed to ultraviolet). The nuclear suspension was then extracted with 1 ml of 0.4 M KCl in 50 mM Tris, *p*H 7.5. After standing for 30 min with occasional agitation, the nuclei were pelleted and the KCl extract containing the ^{3}H-NBcAMP protein complex was analysed by Sephadex G-25 gel filtration for macromolecular bound radioactivity as described in Fig. 2*c* legend.

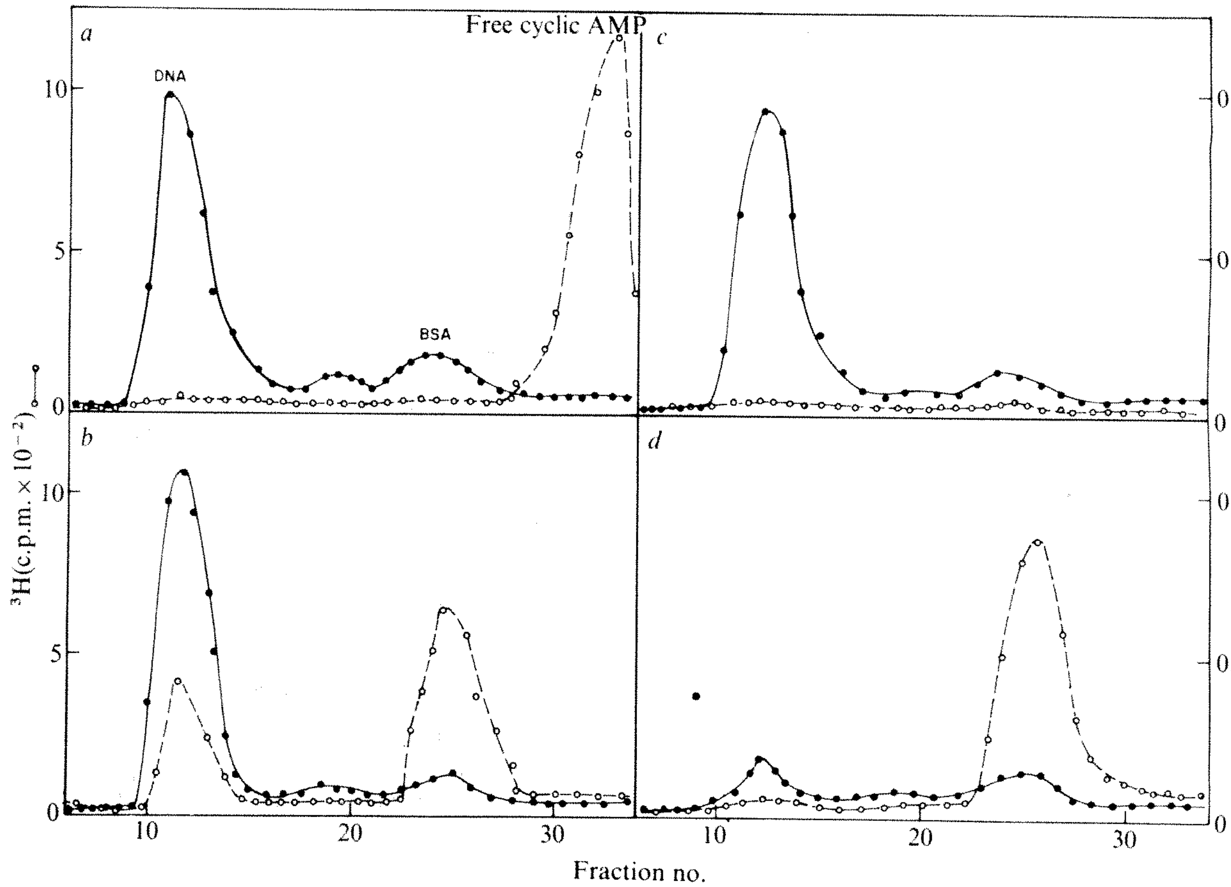
*Nuclei and cytosol were incubated as above and the nuclear suspension was irradiated for 20 min at 4 °C, extracted and macromolecular radioactivity was estimated as above. The amount of released radioactivity from the nuclei is expressed as a % of the nonirradiated control.

†Nuclei and cytosol were incubated with ^{3}H-NBcAMP in buffer C as above, but at 4 °C for 15 min and then irradiated for 20 min at 4 °C. The irradiated suspension was then activated by incubation for 50 min at 25 °C and then extracted and assayed.

‡Nuclei and cytosol were incubated with ^{3}H-NBcAMP for 50 min at 25 °C, then photolysed for 20 min. After irradiation the samples were treated with pancreatic DNase 1 (Worthington, final concentration 0.1 mg ml^{-1} in 50 mM Tris, *p*H 7.5, containing 2 mM $CaCl_2$ and 2 mM $MgCl_2$, incubated for 35 min at 30 °C with occasional shaking and terminated by addition of EDTA, to final concentration of 15 mM). For the DNase control, EDTA was added before the DNase. Extracted radioactivity was then estimated as before (mean of four experiments). The amount of released macromolecular radioactivity in the control was 2120 c.p.m. per 0.35 mg of DNA.

couraged me to explore the receptor labelling in the cell nucleus. Photolysis of the NBcAMP nuclear complex at 254 nm was followed by TCA precipitable counts as a function of time of irradiation. Results of a typical nuclear irradiation experiment (Fig. 2*a*) show that the amount of radioactivity associated with the macromolecules was directly proportional to the time of irradiation. Also, in the absence of irradiation (control), no significant radioactivity was rendered TCA precipitable. The reaction seems to be covalent, as the radioactivity remains associated with the macromolecular fraction during treatments which remove noncovalently bound ligands, such as extensive dialysis against 7 M urea, Sephadex G-25 filtration in the presence of 0.5% SDS, or 10 min boiling with TCA. The photolytic incorporation of ^{3}H into the nuclear macromolecular component seems to be specific, because the reaction could only be prevented by addition of a large excess of non-radioactive cyclic AMP or NBcAMP (Table 1), with no significant competition with other nucleotides such as AMP, ATP and GTP. Further, the photolytic process could not be stimulated in the absence of cytosol, or with cytosol replaced by heat denatured or trypsin treated cytosol, or serum proteins (Table 1*b*). Thus an intact cytoplasmic protein seems to be required for the photochemical reaction, as well as for the non-covalent nuclear binding of NBcAMP.

When the ^{3}H-NBcAMP nuclear complex was incubated in the dark and then subjected to extraction in 0.4 M KCl, most of the radioactive receptor complex was recovered in the extract. When the same complex was irradiated, there was a time dependent decrease in the recovery of the complex this decrease was not seen if the photolysis itself was carried out in the presence of 0.4 M KCl (Fig. 2*b*). About 25% of the radioactive complex can no longer be extracted with salt (as compared with the non-irradiated control), suggesting that a portion of the complex becomes



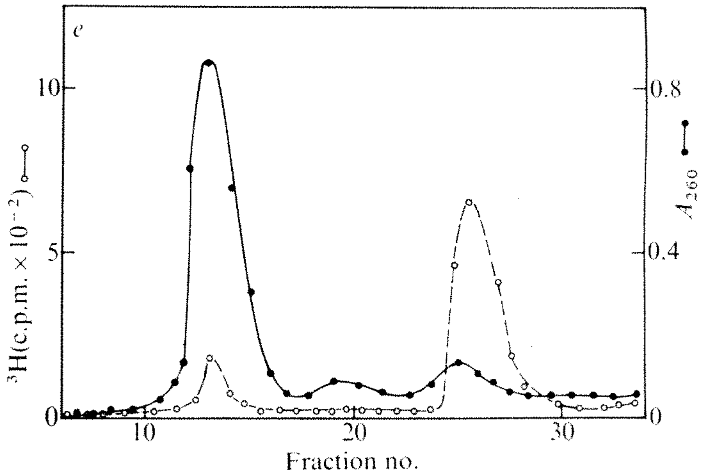


Fig. 3 Characterisation of the irradiated ^{3}H-NBcAMP nuclear complex by SDS Sepharose 2B chromatography. DNA (calf thymus), protein (BSA) and ^{3}H-NBcAMP were used as markers and their respective positions are indicated. Photolysis (for 15 min) of ^{3}H-NBcAMP nuclear complex (1 mg DNA) was carried out as for Fig. 2. In some experiments the noncovalently bound ^{3}H-NBcAMP was removed by TCA precipitation before solubilisation. The TCA or nuclear pellets were then solubilised in about 1 ml of 1% SDS (containing 0.025 M EDTA, 0.05 M metacaptoethanol, 0.1 M Tris-HCl *p*H 8) by heating it at 60 °C for 20 min, with occasional shaking and the sample was applied to a Sepharose 2B column (1.3 × 45 cm) equilibrated (at room temperature) with Tris-SDS buffer (0.15 M KCl, 0.01 M EDTA, 0.05 M mercaptoethanol, 0.1 M Tris-HCl *p*H 8, 0.5% SDS) and 1-ml fractions were collected for determination of absorbancy and radioactivity. After irradiation and before solubilisation, all samples were sonicated (to a DNA molecular weight about 5×10^6). *a*, Elution profile of non-irradiated control was treated identically but not exposed to ultraviolet and to TCA. *b*, Profile of the photolysis sample (with TCA precipitation). *c*, Chromatography of the irradiated complex after trypsin digestion. Following the irradiation, samples were subjected to trypsin treatment (Worthington, final concentration 0.1 mg ml^{-1}, incubated at 30 °C for 45 min, and precipitated with 50% of TCA to final concentration of 10%). The precipitates were collected by centrifugation and washed (sequentially with acetone 3 ml and ether 2 ml) and the pellets were finally suspended in 1% SDS, and analysed by SDS Sepharose chromatography as above. *d*, Chromatography of the irradiated complex after DNase digestion. After photolysis the samples were digested with pancreatic DNase 1 (Worthington, final concentration 0.1 mg ml^{-1} in 50 mM Tris-HCl buffer, *p*H 7.5, containing 2 mM $CaCl_2$ and 2 mM $MgCl_2$ incubated for 40 min at 30 °C with occasional shaking and terminated by TCA precipitation). The digested samples were analysed by SDS Sepharose 2B chromatography. *e*, Irradiation in presence of 0.4 M KCl; ^{3}H-NBcAMP nuclear complex was suspended in 1 ml of buffer C containing 0.4 M KCl irradiated for 15 min as before and analysed by SDS Sepharose 2B chromatography.

'fixed' in the nucleus after 20 min of irradiation. Alternatively, the receptor site may be destroyed during the irradiation, with the radioactive ligand being somehow retained by the nucleus.

If the ^{3}H receptor complex is fixed in the nucleus by covalent attachment, then the nature of the linkage could be characterised by enzymatic digestion. Trypsin and pronase digestion of the photolysed nuclear complex rendered most of the radioactivity TCA soluble (Table 1), but treatment with DNase or RNase did not. DNase treatment, however, resulted in drastic liberation of the fixed ^{3}H-receptor complex from the nuclei, so that the previously fixed radioactivity became extractable with 0.4 M KCl (Table 2). Digestion with DNase suggests that DNA is involved in the nuclear fixation and that the receptor site was probably not destroyed during the irradiation. These experiments are consistent with (but do not prove) the hypothesis that during photolysis the ligand becomes covalently attached to the cytoplasmic receptor and the receptor complex, in turn, is crosslinked to the nuclear DNA.

Specificity of the photochemical reaction

Is the photochemical reaction specific, or is it simply a random collision of free radicals and/or other active species generated during the irradiation process? If the photo-affinity labelling is specific, the reagent molecule would probably bind reversibly and specifically to the receptor site(s), and then bind covalently after photolysis. Thus, conditions which would interfere with specific reversible binding would also prevent covalent binding. I expected first, that a denatured or degraded receptor which is unable to interact either with ligand or with the nuclei would be unable to mediate the photochemical attachment of ligand to receptor or receptor to nuclei. Second, dissociating conditions in 0.4 M KCl which prevent the reversible nuclear binding of the receptor complex should also prevent the photochemical attachment to the nuclei. Third, absence of the heat activation step should have a similar effect. Thus, if the photochemical reaction is specific, then in the absence of reversible binding, there should be no covalent bound formation at the nuclear site.

The results support these predictions. First, degraded receptor did not promote the covalent photoreactions, or the noncovalent nuclear binding of the receptor complex (Table 1). Second, in the presence of 0.4 M KCl when the receptor complex was not associated with the nucleus (Fig. 2*b*), photolysis yielded only affinity labelling at the receptor site, but the receptor was not attached to the nucleus. Third, to verify the heat activation requirement, experiments were carried out in the reverse sequence when the activation (binding) step was preceded by irradiation, again no nuclear linked receptor was observed (Table 2). These results are consistent with the implication that the photochemical reactions are specific: stable links are formed only when substantial noncovalent binding occurs.

Characterisation of nuclear photolysis products

The chemical characterisation of the product formed between ^{3}H-NBcAMP, protein and DNA during irradiation of the nucleus was performed using enzymatic digestions, followed by Sepharose 2B chromatography in the presence of detergent (0.5 SDS) to denature and to dissociate all noncovalently linked molecules. A typical chromatogram of nonirradiated nuclei is shown in Fig. 3*a*. The DNA appeared in the void volume, followed by proteins, and finally by free radioactive ligand. In the presence of the detergent, there was essentially no radioactivity associated with either the DNA or the protein fractions. After 15 min of irradiation, however, there was a striking change in the chromatographic profile (Fig. 3*b*). Two new macromolecular radioactive peaks appeared: the first, in the void volume, coeluted with DNA, and the second, larger peak, appeared with proteins. For the first peak, I have considered the following possible linkages formed during the irradiation between ^{3}H-NBcAMP (cA) and macromolecules: cA–DNA, cA–DNA–protein, DNA–cA–protein, cA–protein–protein(s). These structural alternatives might be distinguished by specific enzymatic digestions. After DNase digestion (Fig. 3*d*), no radioactivity remained associated with the DNA peak, no additional free radioactive ligand was liberated, and all radioactivity migrated with the protein fraction. In contrast, trypsin treatment (Fig. 3*c*) liberated all macromolecular bound radioactivity. Thus, there is probably a protein 'bridge' to link the ^{3}H ligand to DNA, for example ^{3}H–cA–protein–DNA, and there seems to be no direct association between the ligand and DNA.

I have indicated that the dissociating condition prevented both the noncovalent nuclear binding and the covalent attachment of receptor to the nuclei. To substantiate this conclusion, I analysed the chromatographic profile of the reaction products. When the ^{3}H-receptor complex and nucleus were irradiated under dissociating conditions (0.4 M KCl), (Fig. 3*e*), radioactivity was associated mainly with the protein fraction, and only minor amounts with the DNA. Furthermore, when the photolysis was carried out before the activation step, there was essentially no radioactivity in the DNA fraction (data not shown). These experiments further demonstrate that covalent attachment is observed only where substantial noncovalent association occurs.

The alternative that the covalent reaction occurs in the nuclei between the NBcAMP and certain proteins, but without the involvement of the cytoplasmic receptors, is unlikely because essentially no covalent photo-reaction occurs in the absence of the cytosol. It remains possible that the ligand is somehow transferred from its original receptor to another nuclear constituent ('pseudo-photo-affinity labelling', ref. 24). If the nuclear crosslinking product did not involve DNA, this would be difficult to reconcile with the DNase sensitivity of the photo-adduct. Finally, the possibility that a crosslinking reaction occurs with a relatively unspecific part of nuclei, such as nonchromatin material, is also unlikely, as, on photolysis, the same type of crosslinking product was obtained when the nuclei was replaced by purified chromatin (Kallos, unpublished), but not with DNase treated nuclei.

Conclusion

The formation of a stable ternary complex, presumably of covalent nature, has been achieved through specific photolysis of the NBcAMP–protein–nuclei system. The exact chemical nature of the stable joint nuclear complex is not yet known. It probably involves the covalent attachment of NBcAMP to the receptor site and the crosslinking formation between reactive DNA base(s) and protein residues that are in close proximity in the ternary complex.

These results suggest that the optimal noncovalent, as well as covalent, nuclear binding of cyclic AMP require the presence of an intact cytoplasmic receptor. I propose the following reaction sequences (scheme 1) for the reversible interactions (sequence a): (1) the cyclic AMP derivative, NBcAMP (cA), binds specifically and reversibly to a soluble cytoplasmic receptor protein (giving cA·R); (2) this is followed by a temperature-dependent (T°) activation step[19] (cA·R′); and (3) there is an association of this activated complex with the nucleus (cA·R′.N). The photolysis of this reversible nuclear complex (step b) results in the covalent link formation (cA*–R*–N*). The asterisks represent the as yet unidentified photochemically altered components. When the receptor complex is not associated with the nucleus; for example, in the presence of 0.4 M KCl or in the absence of activation, photolysis yields only an affinity label at the cyclic AMP site (cA*–R*), but the receptor is not attached to the nucleus.

The function of the receptor protein, possibly the regulatory subunit of a protein kinase, remains to be determined. It is interesting to note that cyclic AMP dependent protein kinases, which can bind to nuclei (or to DNA), have recently been described in the thymus[25] and in the ovary[26]. Although the photochemical reaction was shown to be specific by several criteria, one must be cautious in the interpretation of the results due to the tendency of the receptors to aggregate[5,27,28].

The particular value of photo-affinity crosslinking is to provide a chemical tool for structural study of the locus of the genome which interacts with the receptor. The present study can only be considered preliminary until the photoproducts are separated and further identified.

This work is dedicated to the late Gordon M. Tomkins (1926–1975), my colleague for 11 years. I thank B. Alberts, V. C. Allfrey, C. B. Anfinsen, R. Axel, C. Cantor, B. S. Cooperman, J. S. Edelman, T. M. Fasy, M. A. Lee, E. Zeff and N. Farber for discussions, and Frances Flug for technical assistance. The work was carried out in Dr Lee's laboratory supported by American Cancer Institute and U.S. Public Health Service grants.

letters to nature

Cosmogony and the magnitude of the dimensionless gravitational coupling constant

SIMPLE arguments involving gravitational fragmentation indicate that for the Universe to contain galaxies and stable nuclear-burning stars, the dimensionless gravitational coupling constant $\alpha_g (= Gm_p^2/\hbar c)$ must lie within several orders of magnitude of its actual value (5×10^{-39}). The characteristic mass of a galaxy is shown to be $\alpha^5\alpha_g^{-2}$ nucleons. If galaxies and galaxy clusters form by gravitational instability and fragmentation of inhomogeneities in the early Universe, the large-scale structure of the Universe imposes a lower bound, and the instability requirement an upper bound (equal to $\alpha_g^{-1/4}$), on the entropy per particle.

Gravity is an exceedingly weak force. A convenient measure of its magnitude is given by the dimensionless constant $\alpha_g = Gm_p^2/\hbar c$ (the ratio of gravitational to electromagnetic forces between a pair of protons multiplied by the atomic fine structure constant $\alpha (= e^2/\hbar c)$, and equal to 5×10^{-39}). The origin and significance of this number have provided a continuing source of speculation among physicists, whose very existence (and indeed the existence of all life) may be contingent on its value[1,2].

Certain elementary and speculative considerations show that for the Universe to contain galaxies and nuclear-burning stars, α_g must lie within a few orders of magnitude of its actual value. In outlining these arguments, I shall also show how the magnitude of one of the most fundamental of cosmological constants, namely the entropy per baryon, can be related to the scale of the large-scale structure of the Universe and the value of α_g. Two significant large number coincidences involving α_g that I will not discuss are the total number of baryons in the observable Universe ($N_u \sim \alpha_g^{-2}$) and the age of the Universe ($\sim \alpha_g^{-1}\hbar/m_pc^2$) (see refs 1–5).

My discussion is based on some recent work[8] on the fragmentation of self-gravitating gas clouds. The concept of gravitational instability was originally presented as a quantitative criterion by Jeans, but Hoyle first stressed the fundamental role of dissipation and fragmentation in gravitational collapse[7]. It is convenient to discuss separately the problems of star and galaxy formation.

Consider a collapsing primordial gas cloud, which can initially be neutral and consist of hydrogen and helium. The cloud will heat up until at $\sim10^4$ K it can cool by excitation of Lyman α-photons, and will continue to collapse approximately isothermally. While the collapsing cloud can radiate freely, it will be gravitationally unstable to fragmentation on smaller and smaller scales, until eventually the individual fragments become opaque either to electron scattering or to H^- opacity. The subsequent, quasi-adiabatic collapse of what one may now identify as protostellar fragments, will be stable against continued fragmentation, provided that the collapsing fragments individually undergo a luminosity-controlled Kelvin–Helmholtz contraction.

To maintain stability, a fragment must be unable to radiate away freely the compressional energy acquired by collapse. The collapse will proceed with $\gamma \approx 1$, and will be unstable to small perturbations: this should manifest itself, however, as convection or turbulence because the ensuing pressure gradients will have a strong stabilising influence on any tendency to further subfragmentation. Sufficiently massive fragments will, however, undergo free-fall, and in this case fragmentation can continue until smaller fragments form that are themselves pressure-supported. This condition can be expressed quantitatively by requiring that the Kelvin–Helmholtz contraction time of a fragment exceed its free-fall time, when the gas temperature is ~0.1 Rydberg (characteristic of hydrogen atom excitations by electron and atom collisions). The Kelvin–Helmholtz contraction time for a protostar of primordial composition, mass M, and luminosity L is $t_{KH} \sim M(kT/\mu)L^{-1} \sim (k/\mu)^5 T\sigma_T G^{-4}(m_p\sigma)^{-1}M^{-2}$, where μ is the mean molecular weight g^{-1}, σ is the Stefan–Boltzmann constant, σ_T is the Thompson cross-section, and T is the central temperature. Since the free-fall time $t_{ff} \sim (G\rho)^{-1/2} \sim GM(kT/\mu)^{-3/2}$, the condition $t_{KH} > t_{ff}$ is equivalent to $M < (k/\mu)^{13/6}T^{5/6}G^{-5/3}(\sigma_T/m_p\sigma)^{1/3}$. One consequently infers that this is equivalent to imposing an upper limit on the mass of a protostar of $N_p \sim \alpha^{7/3}\alpha_g^{-5/3}$ nucleons or about $\sim50\ M_\odot$. For conventional interstellar matter, where the relevant temperature ($\sim10^{-3}$ Rydberg) is determined by the melting of refractory grains, this limiting mass is approximately $0.2\ M_\odot$[8]. Thus typical stars forming now should have relatively low mass (although other effects, notably due to magnetic fields, may enable more massive stars to form), whereas primordial stars are likely to be massive stars.

The mass of a stable nuclear-burning star is known[1-4] to be of order $N_* \sim \alpha_g^{-3/2}$. Apart from numerical factors, less massive stars have degenerate cores, and more massive stars are dynamically unstable. Thus if gravitational fragmentation is to lead to star formation, one evidently requires $N_* \ll N_p$, or $\alpha_g \ll \alpha^{14}$. This upper bound on $\alpha_g (\sim 10^{-30})$ demonstrates the weakness of the gravitational interaction, as determined solely by the requirement that protostellar collapse leads to the formation of stable nuclear-burning stars. If this inequality were violated, stars may still form (compare ref. 9) but would not have undergone a pressure-supported core accretion phase. Such stars may differ drastically from conventional stars; for example, condensation of planets may be inhibited (compare also ref. 2).

Consider next the collapse of a galaxy from an ionised protogalactic gas cloud of arbitrary size but of some specified mass. Such a cloud must initially collapse in adiabatic free-fall, its cooling time ($\propto \rho^{-1}$) being long compared with its free-fall time ($\propto \rho^{-1/2}$). At the instant when the local cooling rate overtakes the collapse rate, if the cloud is moderately inhomogeneous, it will become unstable to fragmentation, and erupt in star formation. The hydrogen cooling rate, due mostly to free–bound transitions at $kT \lesssim 1$ Rydberg, can be expressed as $t_{\mathrm{cool}}{}^{-1} \propto \rho T^{-3/2}$; hence the mass of a gas cloud in gravitational equilibrium satisfies $M \propto \rho^{-1/2} T^{3/2} (t_{\mathrm{cool}}/t_{\mathrm{ff}})$. Since fragmentation into stars proceeds at $T \sim 0.1$ Rydberg, clouds more massive than N_{gal} (defined by $t_{\mathrm{cool}} = t_{\mathrm{ff}}$) must form stars at a much slower rate (by eventually cooling to ~ 0.1 Rydberg). This necessarily qualitative argument suggests that there is a critical mass $N_{\mathrm{gal}} \sim \alpha^5 \alpha_g{}^{-2} (m_p/m_e)^{1/2}$ ($\sim 10^{12}\, M_\odot$) below which clouds can cool within a free-fall time: larger, more slowly evolving, clouds cool relatively slowly and are liable to subfragmentation or disruption by collisions with neighbouring clouds. One infers that N_{gal} is a characteristic mass for galaxies. (One can also show that associated with this mass-scale is a characteristic dimension of 50 kpc.) Since the number of baryons in the observable Universe is of the order $N_u \sim \alpha_g{}^{-2}$ (ref. 3), one infers that the number of observable galaxies should be of the order $N_u/N_{\mathrm{gal}} \sim \alpha^{-5}$, whereas the number of stars in a galaxy is $N_{\mathrm{gal}}/N_* \sim \alpha^5 \alpha_g{}^{-1/2}$. It is amusing that these numbers only coincide if $\alpha_g \sim \alpha^{-20}$.

Introduction of certain cosmological considerations can further our speculations. At present, the Universe is well described by the Friedmann–Lemaitre cosmology, and observations of the microwave background radiation reveal the homogeneity and isotropy of the Universe at early epochs. In such a cosmological framework, primordial curvature fluctuations play an essential role in accounting for large-scale deviations from homogeneity. The scale of initial amplitudes of these fluctuations is not relevant; it suffices to say that the Universe is observed to be lumpy on the scales of galaxies, galaxy clusters and superclusters, and reasonably smooth on much larger scales.

A natural length scale for large-scale structure arising out of the early Universe is the maximum Jeans mass (N_J) which is achieved at the epoch when matter and radiation densities are equal. Shortly thereafter, matter and radiation decouple, and the Jeans mass is drastically decreased. Any disturbances in the radiation era (due to inhomogeneities of finite spatial extent) on scales smaller than N_J will act as a diverging source of waves that propagate out to N_J (in much the same way as water waves are produced by dropping stones into a pond). Neighbouring regions of the Universe similarly develop structure on scale N_J, with the result that structure inevitably develops over the maximum Jeans length in the early Universe (provided one has a sufficiently general form of primaeval inhomogeneity). Fragmentation into galaxies can only occur after matter (density ρ_m) and radiation (ρ_r) have decoupled (at $T \sim 0.02$ Rydberg). One has $N_J \sim c^3 t (G m_p)^{-1}$ when the Universe is still radiation-dominated, with t determined by $\rho_m + \rho_r \sim G^{-1} t^{-2}$, and $\rho_r \sim (kT/hc)^3 (kT/c^2)$.

Consequently, N_J can be expressed in terms of fundamental constants by adopting a temperature equal in order of magnitude to a Rydberg, yielding $N_J \sim S^{1/2} \alpha_g{}^{-3/2} \alpha^{-3} (m_p/m_e)^{3/2}$, or $\sim 10^{16} (S/10^8) M_\odot$. Here the mean entropy per baryon $S \sim 10^8$ is equal to the number of cosmic blackbody radiation photons per hydrogen nucleus and is approximately constant during the course of the nearly isentropic cosmological expansion. We thus account for the order of magnitude of S by noting that N_J must at least be comparable in mass to a supercluster of galaxies. This suggests that the entropy of the Universe is causally related to its large-scale structure.

Strictly speaking, this argument provides only a lower limit on S for an assumed value of α_g; inhomogeneities on scales larger than superclusters could also exist. An upper limit on S is found by requiring that the dynamics of the Universe be matter-dominated (thereby enabling gravitational instability to proceed, to allow formation of galaxies and stars) when the age of the Universe is first comparable with the lifetime of a star. To evaluate this condition, one can set $t = \alpha_g{}^{-1}(h/m_p c^2)$ in the above expression for ρ_r, yielding $kT/m_p c^2 \sim \alpha_g{}^{1/4}(1+\rho_m/\rho_r)^{-1/4}$. Since $S = (\rho_r/\rho_m)(m_p c^2/kT)$, one concludes that, if $\rho_r < \rho_m$, one must S have $\lesssim \alpha_g{}^{-1/4}$. Thus, knowledge of α_g is essential for determining S.

A lower bound on α_g can be obtained independently of S by noting that for galaxies to exist, larger primordial inhomogenities must be present, whence $N_J \gg N_{\mathrm{gal}}$. This condition yields $\alpha_g \gg \alpha^{16} (m_e/m_p)^2 S^{-1}$, and using the upper bound on S just given, one concludes that $S^{-4} \gtrsim \alpha_g \gg \alpha^{64/3} (m_e/m_p)^{8/3} \approx 10^{-44}$. Therefore the finite entropy of the Universe strongly constrains α_g, and is intimately related to the weakness of the gravitational interaction.

The formation of galaxies and stars provides an insight into the magnitude of α_g. Moreover, it seems plausible that the existence of large-scale structure can only occur in a universe with sufficiently great entropy per baryon. Thus one returns (perhaps inevitably) to a modified form of the anthropic hypothesis: gravitational instability and fragmentation must lead from giant clusters to galaxies to stars, and ultimately to planets and an environment suitable for the development of life. This unbroken chain is essential in any cognisable universe, and may therefore provide the key to understanding the significance of the fundamental dimensionless numbers of astrophysics and cosmology.

A method for determining the cosmological deceleration parameter q_0

THE availability of deep plates from the UK 48-inch Schmidt combined with the ability to measure the apparent magnitude of large numbers of images using the Royal Observatory Edinburgh COSMOS machine has made possible a new experiment to determine the cosmological deceleration constant q_0. We have constructed a number–magnitude plot for a large sample of images and compared this with a number of simulated curves representing different values of q_0

The coordinates of the plate centre were: right ascension 2 h 41 min 00 s, declination −30°00′ which is a field near the South Galactic Pole. The plate was exposed for 60 min on December 8, 1974, using a combination of unsensitised Eastman Kodak 098 emulsion and a Schott RG630 filter and was measured on the Royal Observatory Edinburgh COSMOS machine using the coarse measurement mode (CM) (ref 1). The total area of the plate measured was 12.5 × 13.5 cm and the plate scale was 67 arc s min^{-1}.

The CM mode measures the extents, centroids, blackness and area of the images above the plate background. COSMOS currently scans in units of 8 μm using a 25-μm spot full width half height. The image area, A, of principal interest in this experiment is digitised in increments of 8 μm^2.

A is a measure of the area of an image above the computed sky background. The relationship between log A and apparent magnitude m has been investigated[2]. These results, from a number of Schmidt plates, show the relationship to be linear, of the form

$$m = b \log A + \text{const} \qquad (1)$$

throughout the range $1.0 \leqslant \log A < 2.2$. The parameter b varies slightly from plate to plate, as may be expected, and in the present case, $b \approx 3.5$.

A total of 41,225 images was detected above the plate threshold but only images of 10 increments or greater were included in the analysis. This corresponds to a minimum image size of 1.77 arc s while the plate was taken in seeing of ~ 1 arc s. The number of images N, in each digitised area bin A was plotted logarithmically in Fig. 1.

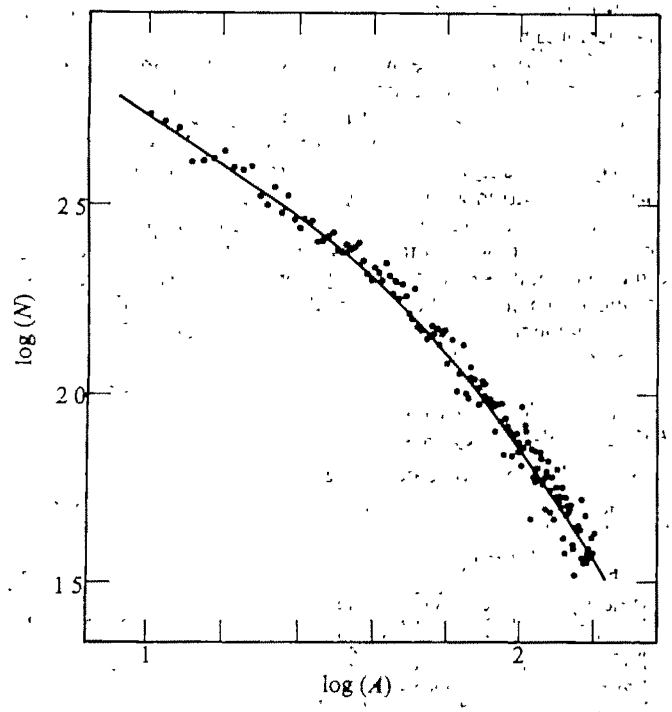

Fig. 1 Log (N)–log A relationship showing best fit curve to observed data. Dots represent number of images in each area bin.

A preliminary examination of the log N–log A plot in Fig. 1 shows a noticeable change in slope in the region of log A = 1.5. To determine the cause of this a simulated number–magnitude plot was constructed on the basis of the absolute fluxes for galaxies given in ref. 3. The procedure adopted was as follows. k-corrections were evaluated by computer for each galaxy type with the effective wavelength bandpass given by the filter–photographic plate combination described above. The k-correction is applied to the apparent magnitude to compensate for the Doppler shift of the spectrum across the filter combination and is a function of the galaxy type. It is defined by

$$k(z) = 2.5 \log(1+z) + 2.5 \log \left(\frac{\int_0^\infty F(\lambda) S(\lambda)\, d\lambda}{\int_0^\infty F\left(\frac{\lambda}{1+z}\right) S(\lambda)\, d\lambda} \right) \qquad (2)$$

where F is the intrinsic flux distribution of the galaxy as a function of wavelength and S is the effective detector response.

Mattig[4] has shown that a galaxy of absolute magnitude M at redshift z will have an apparent magnitude m, which, with the addition of the k-correction, is given by

$$m = M + 5 \log D(z) + k(z) + \text{const} \qquad (3)$$

where $$D(z) = \frac{1}{q_0^2} \left\{ q_0 z + (q_0 - 1)(\sqrt{(1+2q_0 z)} - 1) \right\} \qquad (4)$$

and q_0 is the deceleration parameter.

The predicted number of galaxies of magnitude m is calculated by computing the volume of space at that redshift. This is given by Mattig as

$$N = \begin{cases} (1-2q_0)^{-3/2}\,(\varphi\sqrt{(1+\varphi^2)} - \text{arc sinh}\,\varphi) & q_0 < \frac{1}{2} \\ 16/3\ D^3(1+D+\sqrt{(1+2D)})^{-3} & q_0 = \frac{1}{2} \\ (2q_0-1)^{-3/2}\,(\text{arc sin}\,\varphi - \varphi\sqrt{(1-\varphi^2)}) & q_0 > \frac{1}{2} \end{cases} \qquad (5)$$

where $$\varphi = \frac{D\sqrt{|2q_0 - 1|}}{q_0(1+D) - (q_0-1)\sqrt{(1+2D)}}$$

(D defined as in equation (4)).

This calculation is repeated for a range of values of z. The frequency distribution of the absolute magnitudes of galaxies of a particular type is believed to be Gaussian. This luminosity function is given by Pence[3] for various galaxy types.

The calculation of the apparent magnitudes was repeated for each galaxy type throughout the range of absolute magnitude, and the total number of each apparent magnitude was then weighted according to the luminosity function. The entire process was repeated for each galaxy type to give the overall distribution of apparent magnitudes.

Thus the predicted relationship between log N and m was obtained for a given q_0. The simulated curves showed a change in slope over a range of values of q_0. This is attributable to a marked change in the value of the k-correction due to a broad absorption feature being red-shifted into the filter combination. This suggested the possibility of fitting the simulated data to the observed by varying the value of q_0 in the simulation. To achieve this, the simulated log N–m relationship was evaluated for values of q_0 in the range $0 \leqslant q_0 \leqslant 2$ in intervals of 0.1. To determine the minimum r.m.s. difference between the observed and the simulated curves it was necessary to fit for zero points of the simulated log N and m axes since these were not included in the simulation. This process provided a best fit value for q_0. This value, however, was somewhat dependent on the scaling factor of the magnitude axis which had been included in the simulation (variable b to equation (1)). Therefore, due to the uncertainty in b it was decided to fit this parameter as well. As a crosscheck, we tested the consistency of the method by fitting for a scaling factor in the log N axis.

The fitting was done by a combination of analytic and iterative computer processes for each value of q_0; this is equivalent to laying the simulated data on the observed, and aligning and stretching the axes in order to give the minimum r.m.s. deviation between the two curves.

The minimum r.m.s. for each value of q_0 is plotted in Fig. 2. There is a minimum in the region of $q_0 \simeq 0.8$. The solid line represents the best fit cubic polynomial to these points, which has its minimum value at $q_0 = 0.81$. The formal s.d. in the fit is $q_0 = \pm 0.04$. A more realistic error is obtained, however, by taking the limits defined by applying the r.m.s scatter about the best fit to the minimum point which gives $q_0 = 0.8 \pm 0.3$. The simulation corresponding to $q_0 = 0.8$ is plotted as a solid line in Fig. 1.

The magnitude scaling factor obtained from the best fit was $b = 3.45$, which compared favourably with the predicted value 3.5. The log N scaling factor was expected to be 1.0. Evolutionary effects would tend to increase this value, however, implying that objects were either more numerous or brighter in the past. The value obtained was 1.05, which does not differ far enough from unity to indicate a significant evolutionary effect. The smallness of the deviation from unity indicates, however, that the simulation was an adequate model for the observed distribution.

The possibility of effects other than the *k*-correction (for example, some data acquisition error) were examined to see if they were capable of causing the shape of the observed distribution.

Extensive tests carried out with COSMOS recently indicate that for image areas greater than 10 increments the systematic errors in the measured areas are small. The smallest images used in the analysis are at least one magnitude above the plate limit and the critical change in slope is approximately 2½ magnitudes above the plate limit. Photographic effects such as reciprocity failure have negligible effect on the image size at this level. A possible source of error is the construction of the model used in the simulation. It is now generally accepted that galaxies were intrinsically brighter in the past[5]. This means that any method of evaluating q_0 which relies on measuring apparent magnitudes should make allowances for evolutionary effects, which tend to increase the measured value of q_0. This has been discussed in recent papers in which the magnitude–redshift relationship is used to evaluate q_0[6], but as the evolutionary processes involved remain uncertain, it was decided to exclude them from this model. Similarly, effects due to intergalactic absorption, which would tend to decrease the measured value of q_0, but which also are uncertain, have also been ignored. However, the proximity of the log *N* scaling factor to unity gives weight to the argument that the sum of these effects is small.

One possible source of error in the model was the absence of stars in the simulation although some stars will appear in the observed data. It may be deduced from recent observations of the stellar luminosity function near the South Galactic Pole that the proportion of stars to galaxies in the observed data is probably small[7,8]. Nevertheless, an attempt was made to incorporate stars into the simulated model, but the effects were small. The value of q_0 could be reduced by up to ~0.4, but at present there is a large uncertainty in the stellar luminosity function at these magnitudes. Therefore for the final result the stars were excluded. It should be pointed out, however, that a proportion of the images in the observed data were of 'stellar' appearance. It is probable that these objects are predominantly distant galaxies where only the compact central region is observed, as would be expected from known galaxy profiles.

Again, the derived scaling factor of the log *N* axis indicates that there was no appreciable contamination of the data by stars.

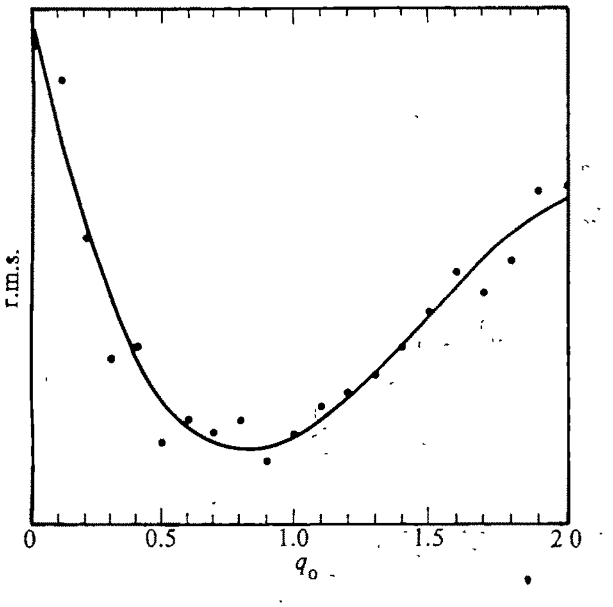

Fig. 2 r.m.s. deviation of best fit curve for each value of q_0 from the observed data in Fig. 1.

The result of this experiment gives a formal value

$$q_0 = 0.8 \pm 0.3$$

It should be possible to estimate the size of some of the possible systematic errors by further analysis of independent samples. We intend to repeat the experiment with deeper plates and a calibration system that is currently under development.

This experiment has the advantage that the observed data may be assumed to contain a complete sample of intrinsic galaxy types throughout the redshift range considered. This means the estimated value of q_0 is independent of the Hubble constant and the absolute magnitude of the galaxies.

We thank Professor V. C. Reddish for his encouragement and interest in this project, Dr N. M. Pratt for measuring the COSMOS data and Mrs G. Pickup for making available results on the magnitude calibrations prior to publication.

Sunspot cycles and solar activity forecasting

I REPORT here that there is a linear relation between the relative intensity of solar cycle activity, as measured by the ratio (μ) of maximum annual mean sunspot number of two consecutive cycles, and the relative skewness of the first cycle. This relationship facilitates the forecasting of the intensity of the next cycle towards the end of a current cycle. The solar cycle just starting is likely to be more active, with an expected maximum annual average sunspot number of 195, compared with 106 for the cycle just ended.

The solar cycles as represented by the mean annual sunspot number for the period of observations beginning in the year 1756 reveal no obvious pattern in the variations of solar cycle activity as measured by the maximum annual sunspot number. The cycles are all asymmetrical. The degree of asymmetry of the cycles may be represented by the statistical parameter of relative skewness (β), where

$$\beta = \frac{m_3}{\sqrt{(m_2^3)}} \qquad (1)$$

and m_3 is the third moment about mean, or $(\Sigma f_i x_i^3)/\Sigma f_i$, with f_i the frequency and x the deviation about the mean; $m_2 = S^2$ is the second moment about mean the S and the standard deviation.

In general, the greater the sunspot activity, the more positive the cycle skewness; this is illustrated in Fig. 1. Cycles with R_{max} (maximum annual mean sunspot number) less than 100 have $\beta < 0.35$ (with one exception), and cycles with higher R_{max} have $\beta > 0,35$ (with two exceptions). In Fig. 2 the β values of the cycles are plotted against the ratio μ of the R_{max} of the next

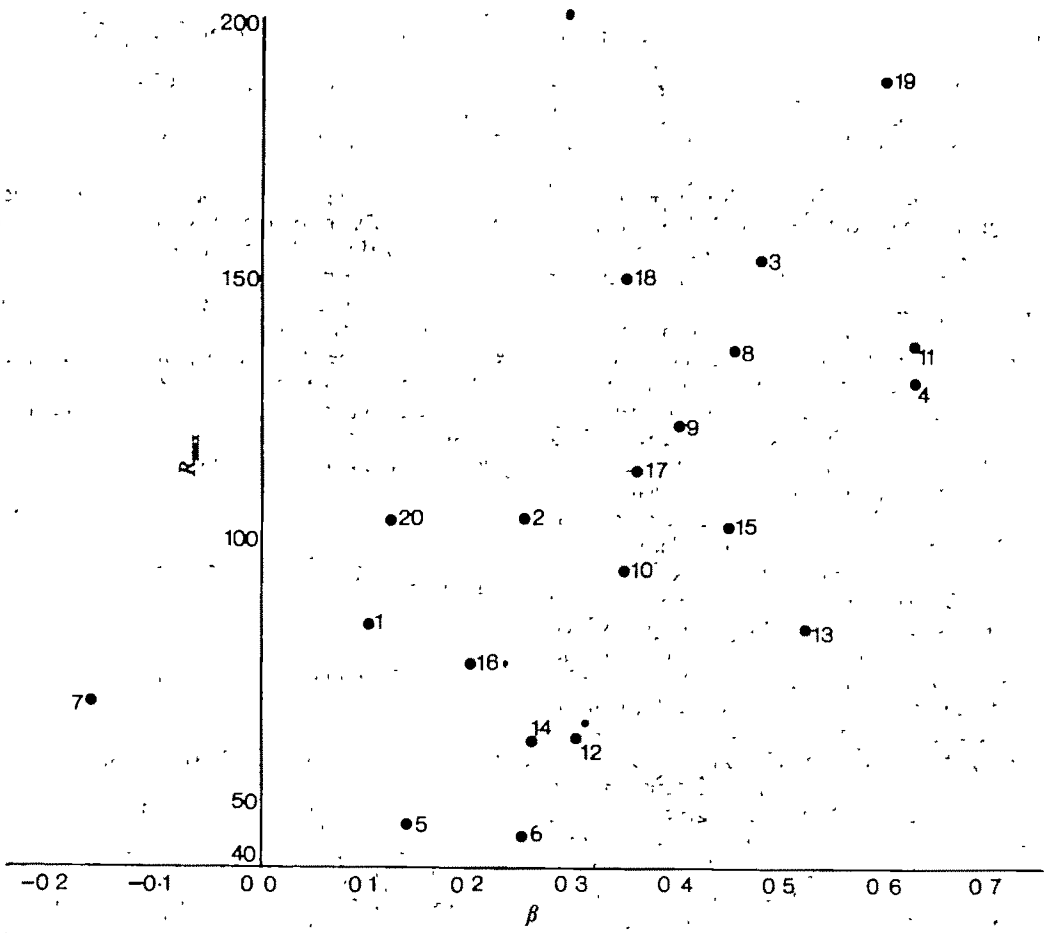

Fig. 1 R_{max} of cycle (mean annual sunspot no.) at various values of cycle skewness (β). Numbers against points are cycle numbers from cycle 1756–1766.

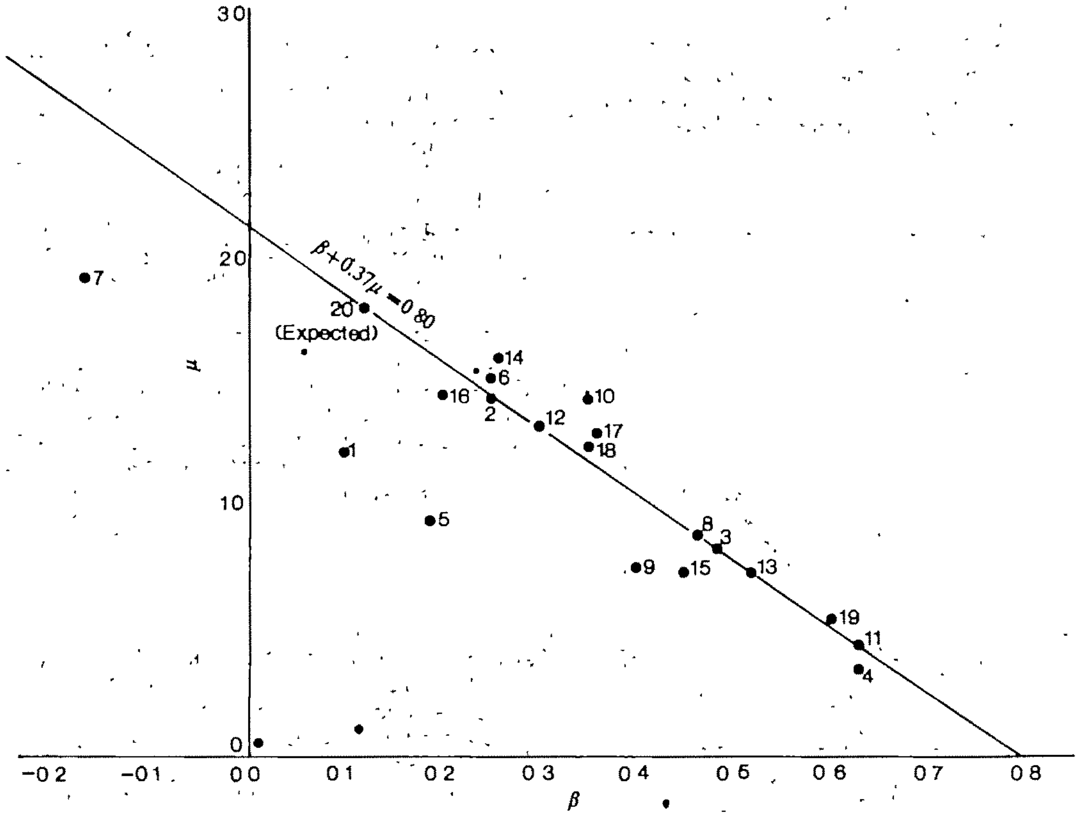

Fig. 2 Ratio of R_{max} of next cycle to R_{max} of current cycle (μ) for various values of β Numbers against points are cycle numbers from cycle 1756–1766.

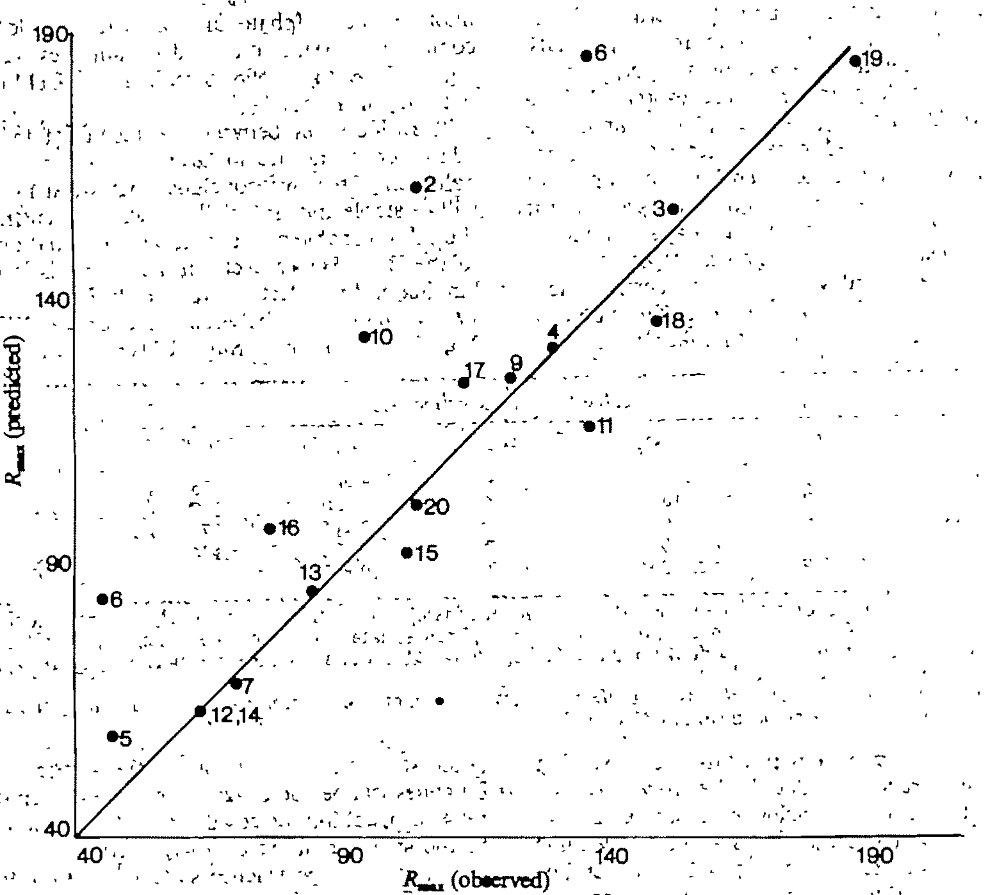

Fig. 3 Predicted and observed values for $R_{\max}$. Numbers against points are cycle numbers from cycle 1756–1766.

cycle and $R_{\max}$ of a current cycle. This plot exhibits linearity and may be represented as

$$\beta + 0.37\,\mu = 0.8$$

Figure 3 is a scatter plot of the observed $R_{\max}$ values of the cycles against the $R_{\max}$ values derived from the above linear relation. The scatter about the equidistant line is less than 15% for all but five of the 19 cycles plotted and 50% of the cycles show less than 5% error.

The above empirical relation was established in 1965 (G.R., unpublished thesis), and verified for cycle 20 just ending. Extending it to the coming 21st cycle, it seems that this cycle should be very active. The formula predicts that activity will increase by 1.84 times the activity of the previous (20th) cycle. The expected intensity may thus be close to that of the 19th cycle which was the most active in 200 yr. In 1978, or within 3 yr of the onset of the new cycle, this sunspot high may be observed.

Theoretical chemistry of superheavy elements E116 and E114

RECENT evidence[1] for the presence of primordial superheavy elements 126, 124, 116 and possibly 114 in microscopic crystalline monazite inclusions in biotite micas raises several interesting questions. Earlier work[2,3] suggested reasons why E124 and E126, the homologues of U and Pu, respectively, might occur in such an environment, but gives little information about E116. Better information on both E114 (eka–Pb) and E116 (eka–Po) could enable us to see why they might occur in these minerals and help suggest methods of concentration. At present, *ab initio* relativistic structure calculations for molecules containing superheavy elements are not feasible. We have developed techniques, however, for studying the structure of heavy atoms and ions using the multi-configuration Dirac–Fock (MCDF) relativistic self-consistent field method[4]; this is a considerable advance on the single configuration Dirac–Fock or Dirac–Slater techniques previously available[2,3]. Applications of the MCDF method to atoms and ions of Ba, Hf (Ref. 4), Bi and U, for example, have yielded good ionisation potentials and energy spectra, mainly due to the way in which relativistic effects, which increase dramatically in size with atomic number[2–4], are handled. These effects make it difficult to predict some chemical properties of superheavy elements by extrapolation from the Periodic Table. We use here, therefore, the results of MCDF calculations of some properties to estimate the heat of formation of simple compounds of E114 and E116 with the simple ionic model[5] and with Pauling's semi-empirical valence-bond resonance model[6], to acquire insight into the chemistry of these elements.

The atomic data required are listed in Table 1. Ionisation potentials (IP) were obtained from energy differences of MCDF ground states of the relevant ions, whenever no reliable experimental value was available, adding an energy of 77 kJ mol^{-1} to correct for correlation effects not allowed for in the calculation[2,3]. Ionic radii were estimated from the mean radius of the outermost Dirac–Fock orbital using a method to be reported elsewhere; for E114^{+2}, this estimate differs by 0.01 Å from the value linearly extrapolated from Sn^{2+} and Pb^{2+}. Lattice energies were estimated from the Kapustinskii equation (ref. 5), taking $\rho = 0.345$ in the Born–Mayer repulsion formula. The overall uncertainty in the lattice energy is too small to affect our conclusions; we shall report the details of our investigations elsewhere. Heats of sublimation, if not available, were estimated by extrapolating down the relevant group of the Periodic Table; their contribution is dominated by the ionisation potentials, and extrapolation errors are unimportant for our purposes.

The data for the covalent model[6] were estimated in a similar way. The MCDF program was used to compute the energy, E_v, needed to excite a superheavy atom to a valence state which can form strong bonds. This is an important contribution for E116 and E114, whose ground states are almost pure jj coupled; such states contain a substantial anti-bonding component[6]. Homonuclear bond strengths, *D*(X–X), were estimated following Phillips and Williams[7], and heteronuclear bond strengths, *D*(X–Y), from Pauling's formula[8]. The unknown electronegativities, χ_v, were found from Mulliken's formula[8], using MCDF estimates of ionisation potentials and electron affinities. Again, we shall report the details elsewhere.

Table 1 Atomic properties

Atom	r_{+2} (Å)	r_{+4} (Å)	ΔH_s	IP_2	IP_4	E_v*	χ_v	*D*(X–X)
Te	1.28	0.94	197	2,665	8,966	75	2.1	138
Po	1.32	0.97	142	2,364	8,640	197	1.8	105
E116	1.35	1.01	109	1,937	8,711	577	2.0	79
Pb	1.21	0.84	197	2,167	9,330	134	1.8	109
E114	1.29	0.91	126†	2,531	10,247	427	1.6	96

Heats of sublimation (ΔH_s), ionisation potentials (IP_2/IP_4 for removal of two/four electrons, respectively), valence excitation energies (E_v) and homonuclear bond strengths (*D*(X–X)) are in units of kJ mol^{-1}. Experimental data have been used, when available, for Te, Po and Pb.

* E_v is the promotion energy for divalent p-orbital bonding. The sp^3 tetrahedral quadrivalent state of E114 requires a promotion energy of 1,665 kJ mol^{-1}, making such compounds unlikely.

†This is probably an upper bound. Keller *et al.*[2], using a different extrapolation, give 42 kJ mol^{-1}, which would make the predictions of ΔH_f for E114 compounds in Tables 2–4 more stable by about 84 kJ mol^{-1}.

Some care is needed in drawing conclusions from Tables 2–4. We use enthalpy instead of free energy to assess thermodynamic stability; however, the difference is too small to affect our conclusions at room temperatures[11]. An endothermic compound ($\Delta H_f > 0$) is not necessarily unstable (e.g. H_2Te). An exothermic compound ($\Delta H_f < 0$) is stable against decomposition to the free elements, but can still be unstable with respect to other decomposition or disproportionation reactions. It seems reasonable to predict that a compound is definitely covalent or ionic if the difference in the respective values of ΔH_f is sufficiently large, say 200 kJ mol^{-1}.

Table 2 Predicted heats of formation of dihalides (kJ mol^{-1})

	Ionic model				Covalent model (gas phase)				
Atom	F^-	Cl^-	Br^-	I^-	F	Cl	Br	I	H
Te	−79	297	410	598	−561*	−272	67	163	134
Po	−397	−29	79	264	−699	−46	67	201	213
E116	−837	−473	−335	−155	−163	418	514	623	611
Pb	−628	−238	−121	71	−707	−54	59	192	205
E114	−272	100	218	402	−644	84	209	360	406

*Covalent TeF_2 is unknown, presumably because it is unstable with respect to disproportionation to covalent TeF_4+Te.

Thus, we predict that E114 should be less reactive than Pb, mainly because IP_2 is 313 kJ mol^{-1} larger than one would expect by extrapolating from Sn and Pb. Other contributions to ΔH_f vary smoothly down the group, so that this relativistic atomic effect dominates. The ionic–covalent resonance term, which may here be slightly overestimated, is responsible for the relatively large covalent energy of $E114.F_2$. Although the gaseous halides, other than the fluoride and, possibly the chloride (Table 2 footnote) seem to be endothermic, the ionic fluoride and sulphate are predicted stable, contradicting a conjecture[6], based on cruder estimates (E_v(Pb) = 192 kJ mol^{-1}, E_v(E114) = 598 kJ mol^{-1}), that E114 might behave as a relatively inert gas.

Table 3 Predicted heats of formation of divalent inorganic salts using the ionic model (kJ mol^{-1})

Atom	SO_4^{2-}	CO_3^{2-}	NO_3^-	PO_4^{3-}
Te	−226	−21	180	−347
Po	−552	−343	−151	−1,318
E116	−971	−782	−569	−2,641
Pb	−761	−569	−356	−1,983
E114	−418	−213	−17	−929

The differences between the results of the two models for E116 compounds are so large, and so different from those for polonium, that we conclude that divalent halides of E116 will be stable and essentially ionic, and that the salts of Table 3 should be capable of preparation. Examination of contributions to the Born–Haber cycle shows that this is due to the weak binding of $7p_{3/2}$ electrons (ε = 632 kJ mol^{-1}); the value of IP_2, 1937 kJ mol^{-1}, lies between those for Ca (1736 kJ mol^{-1}) and Mg (2188 kJ mol^{-1}). Since $E116^{2+}$ has a larger ionic radius (1.35 Å) than Mg^{2+} (0.68Å), the lattice energies of E116 dihalides will be about 420 kJ mol^{-1} less than those of Mg. The relative instability of covalent E116 compounds is mainly due to the strong binding of $7p_{1/2}$ electrons (ε = 1414 kJ mol^{-1}) leading to a large valence state promotion energy of 577 kJ mol^{-1}. The E_v and χ_v are larger than expected from extrapolation down Group VIB.

The reliability of our models for E116 can be assessed from the corresponding results for Te and Po. We conclude that tellurium dihalides are all covalent, in agreement with known chemical properties, whilst $TeCO_3$ and $Te(NO_3)_2$ are almost certainly unstable with respect to the oxide, and complex tellurium sulphates are known[10]. Similarly, the emergence of cationic properties for polonium is correctly predicted.

The ionic radius of $E116^{4+}$ (1.01Å) and the energy required to ionise the two $7p_{1/2}$ electrons (6774 kJ mol^{-1}) are larger than those of Po^{4+} (0.97 Å and 6276 kJ mol^{-1}), making its quadrivalent ionic compounds less stable than those of polonium. Whilst polonium forms volatile $PoCl_4$, $PoBr_4$ and PoI_4, which are presumably covalent in the gas phase, the E116 analogues seem unlikely to be stable. The covalent dihalides seem to be strongly endothermic, and the energy released by forming two more bonds would not be sufficient for stability when the promotion energy of a p^3d valence state is taken into account. Hexavalent E116 compounds seem unlikely to be stable because the $7s$–$7p_{3/2}$ energy gap (2063 kJ mol^{-1}) is much larger than the corresponding $6s$–$6p_{3/2}$ gap (1330 kJ mol^{-1}) in polonium.

We conclude that the chemistry of E116 should be mainly cationic; although it is in Group VIB, we expect it to form divalent ionic compounds with an ease approaching that of beryllium or magnesium, and quadrivalent compounds with the most electronegative atoms. The element might reside in monazite as

Table 4 Predicted heats of formation of quadrivalent compounds using the ionic model (kJ mol^{-1})

Vacuum ultraviolet radiation scales

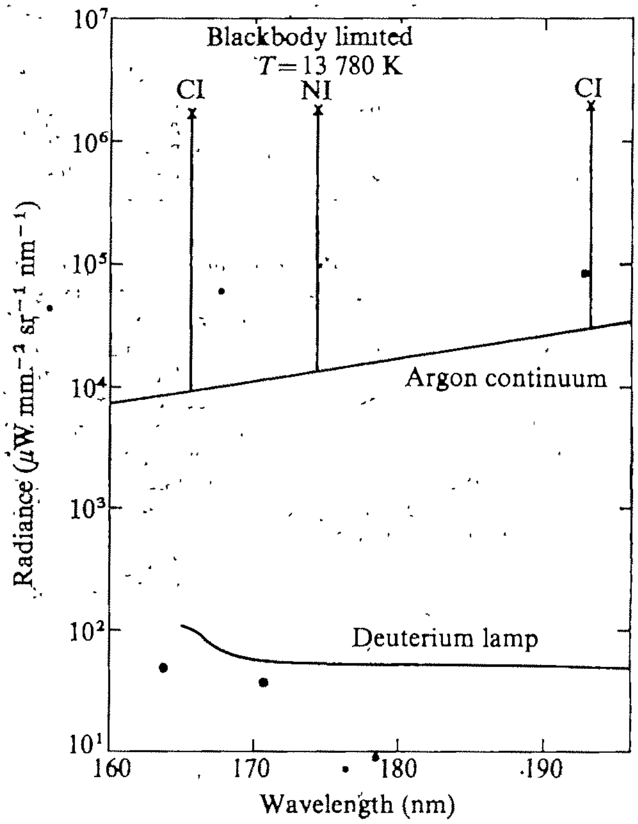
WE report here a comparison of two independent techniques (high-temperature argon arc and synchrotron radiation) for the determination of vacuum ultraviolet spectral radiances. Basic agreement between the methods has previously been demonstrated at 165.7 nm by Stuck and Wende[1], but we have refined the techniques to produce significant improvements in accuracy and have extended the comparison to other wavelengths.

The addition of trace gases to a high-temperature wall stabilised argon arc results in the production of optically thick resonance lines (for example from C, Kr, N, O) at wavelengths predominantly in the vacuum ultraviolet[2]. The determination of the blackbody limited spectral radiances at the centres of these lines requires only a measurement of plasma temperature. Recent research at NPL (R.C.P., in preparation) has produced increased accuracy in such temperature determinations (±55 K at 13,800 K) as a result of the application of various plasma diagnostic techniques. There have also been refinements in techniques for producing saturation of the resonance line radiation with minimal perturbation to the plasma, and in correcting for the effects of the residual perturbation. As a result, resonance line radiances can be established with a marked improvement in accuracy, for example ±3.2% at 165.7 nm and ±2.6% at 193.1 nm.

The method based on the predictable spectral emission properties of synchrotron radiation[3,4] is well established. In the past few years we have used several different experimental techniques, with both the Glasgow University and the SRC Daresbury synchrotrons, to set up an accurate ultraviolet spectral emission scale (P.J.K., in preparation), initially down to 200 nm. The synchrotron radiation has been used only as a standard of relative spectral distribution, since the circulating electron current cannot be measured with sufficient accuracy to establish absolute levels. These are therefore set by comparison at about 350 nm with existing visible/near-ultraviolet standards based on conventional blackbody radiators. Work at Daresbury has extended this scale into the vacuum ultraviolet, currently to a limit set at about 165 nm by the availability of suitable transfer standard sources. These are normally deuterium discharge lamps, producing continuum radiation from 165 to 370 nm, and are specially modified and selected versions of commercially available lamps, with ageing rates of less than 0.05% per h at all wavelengths. The accuracy now attainable in the calibration of these sources is estimated as ±2.7% at 200 nm and ±3.6% at 165 nm.

To effect the intercomparison, four deuterium lamps were calibrated using synchrotron radiation and their spectral radiances then determined by the argon arc method at the three resonance lines, 165.7 nm (CI), 174.3 nm (NI) and 193.1 nm (CI). The measurements were made with a very high resolution concave grating monochromator to investigate adequately the saturation of the peak of the blackbody resonance lines. The aperture ratio of the optical system (f/260) was determined by the aper-

Fig. 1 Radiances of resonance lines, argon continuum and a typical deuterium lamp.



tures in the differential pumping system and by the need to restrict the field of view to regions of adequate temperature uniformity. The arc was 55 mm long and run at 60 A in argon at a pressure of 1.75×10^{5} Pa, producing an axial temperature of 13,780 K. The radiance levels of the line peaks, the argon continuum and a typical deuterium lamp are shown in Fig. 1. Because of the large dynamic range, the intercomparison was made by first measuring the ratio of resonance line peak to argon continuum and then, with an increased exit slit width, the ratio of argon continuum to deuterium lamp radiance.

A major experimental problem arose because the spectral distribution of the deuterium lamp radiation varied significantly from the centre to the edge of the 1-mm diameter emitting area. Synchrotron measurements were based on a 0.9-mm diameter sample, arc measurements on a 0.2×0.03 mm central spot, and detailed investigation revealed correction factors that were large and very wavelength dependent, especially at shorter wavelength (~7% at 165.7 nm). Another difficulty at 165.7 nm was the onset of the complex deuterium molecular line emission spectrum superimposed on the continuum. Different spectral bandwidths in the synchrotron and arc calibration systems required computer-based convolutions of a high resolution deuterium spectrum to reduce radiance measurements to the same bandwidth conditions. Since the calculated correction factors were very sensitive to wavelength, a further measurement of the deuterium lamp emission was made at 167 nm, away from the line emission, by comparison with the argon arc continuum. This continuum level was in turn obtained by comparison with the 165.7-nm line, the change in instrumental response over this wavelength interval being small enough to be measured with adequate accuracy.

The results of measurements on the four lamps are shown in Table 1. The result at 167 nm is based on the 165.7-nm resonance line realisation and so is not totally independent; the difference clearly reflects the problems of the bandwidth and area correction factors. Total intercomparison uncertainties range from 0.9% at 193.1 nm to 2.4% at 165.7 nm and the radiance ratios for all lamps are within the expected limits set by combined intercomparison and basic scale realisation uncertainties. The agreement averaged over the four lamps is extremely good and we conclude that the two methods for establishing vacuum ultraviolet radiances are in agreement to well within their individual scale uncertainties.

Table 1 Ratios of deuterium lamp radiance determined from arc measurements to that from synchrotron measurements

Wave-length (nm)	Lamp no. 786	787	808	810	Mean
165.7	1.009	1.039	1.016	0.993	1.014
167	0.987	1.000	1.004	0.969	0.990
174.3	1.012	0.987	0.998	0.991	0.997

Volatilisation of methylmercuric chloride by hydrogen sulphide

THE interconversion of mercury compounds in the environment has attracted considerable interest, especially the synthesis and breakdown of the highly toxic methylmercury. The alkylmercurial can be formed and degraded by microorganisms in lakes, rivers, soil and the mammalian intestinal tract[1–6], although the ecological significance of these processes is difficult to assess. We describe here a further reaction which may be important with respect to the fate of mercury in the biosphere—the interaction of methylmercuric chloride (CH_3HgCl) with hydrogen sulphide. Hydrogen sulphide is produced by many bacteria in anaerobic conditions such as are found in the sediments of lakes and rivers, and it has been shown that trimethyllead salts can be converted to the volatile tetramethyllead by reaction with H_2S (ref. 7).

Methylmercuric chloride labelled with ^{203}Hg (Radiochemicals Centre, Amersham), or ^{14}C (New England Nuclear) was purified by extracting it from aqueous solution into benzene, evaporating the organic solvent and redissolving the residue in distilled water.

When solutions of the purified CH_3HgCl were incubated in the presence of H_2S, radioactivity was lost from aqueous solutions within 3–4 d, the rate of loss of radioactivity being similar whether ^{14}C- or ^{203}Hg-labelled CH_3HgCl was used. Analysis of the solutions by thin-layer chromatography revealed that all remaining radioactivity was present as CH_3HgCl. When N_2 or air was used instead of H_2S, or when the bottles were incubated under H_2/CO_2 (97%/3%) in an anaerobic jar (GasPak, BBL Ltd), little or no radioactivity was lost (Fig. 1 and Table 1). Other sulphur compounds, such as cysteine and sodium thioglycollate, did not induce volatilisation of CH_3HgCl and although ammonium sulphide did cause some loss of radioactivity, this may be ascribed to the slight dissociation of the ammonium sulphide with the formation of small

Fig. 1 Volatilisation of CH_3HgCl by H_2S. Solutions of the purified $^{14}CH_3HgCl$ (0.01 μCi μg^{-1}, final concentration 2 μg ml^{-1}) or $CH_3{}^{203}HgCl$ (0.025 μCi μg^{-1}, final concentration 2 μg ml^{-1}) were incubated at 37 °C in screw-cap bottles fitted with rubber septa. H_2S was passed into some of the bottles through hypodermic needles for 2 min before incubation. Samples were taken from the bottles at various times using a syringe and hypodermic needle, so that the atmosphere above the solution was not unduly disturbed. The samples were assayed for residual radioactivity in the solution and for the amount of radioactivity associated with CH_3HgCl by thin-layer chromatography as described previously[4]. ○, $CH_3{}^{203}HgCl$, air; ●, $CH_3{}^{203}HgCl$, H_2S; △, $^{14}CH_3HgCl$, air; ▲, $^{14}CH_3HgCl$, H_2S.

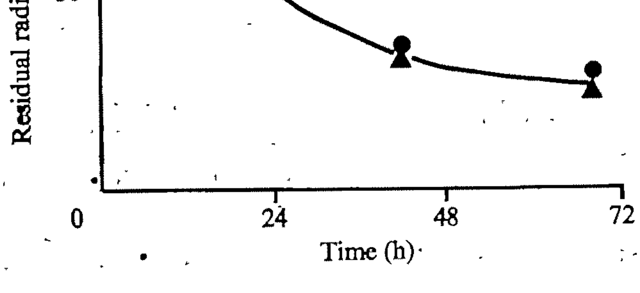

Table 1 Effect of certain gases and sulphur compounds on volatilisation of $CH_3{}^{203}HgCl$ from solution

Compound or gas	Residual radioactivity
Air	98.0±1.2
Nitrogen	97.1±0.9
Carbon dioxide	93.4±1.1
Hydrogen/carbon dioxide (97%/3%)	93.6±2.1
Methane	95.1±1.6
Hydrogen sulphide	30.6±3.0
Sodium sulphide	100.0±0.8
Ammonium sulphide	77.2±1.8
Methionine	97.4±0.5
Cysteine HCl	99.6±1.9
Sodium thioglycollate	98.8±1.6
Sodium thiosulphate	101.6±2.4

Aqueous solutions of $CH_3{}^{203}HgCl$ (2 μg ml^{-1}, 0.05 μCi μg^{-1}) were incubated for 44 h at 37 °C in the presence of the above substances. The final concentration of the solid compounds was 10 mg ml^{-1}. The results are expressed as percentage of initial radioactivity remaining after 44 h. Figures shown are the means ± s.e. of five results.

amounts of H_2S (Table 1). The inability of the strong reducing agent sodium thioglycollate to volatilise CH_3HgCl suggests that the effect of H_2S on the alkylmercurial is not simply due to the reducing capacity of H_2S. Furthermore, H_2S did not reduce inorganic mercury to metallic mercury (unpublished observations of I.R.R.), which may be compared with the results of De Filippis and Pallaghy[8], who found that acetylene and ethylene could reduce mercuric salts to mercury metal. The volatilisation of CH_3HgCl cannot be ascribed to the acidic character of H_2S, even though the *p*H of the CH_3HgCl solution had decreased from 6.5 to 4.0 by the end of the incubation. Experiments in which CH_3HgCl was incubated in air or H_2S in the presence of buffers of *p*H 2.2–8.5, demonstrated that the *p*H of the solution had little influence over the rate of volatilisation by H_2S and, furthermore, in the absence of H_2S, virtually no radioactivity was lost at any of the *p*H values.

The rate of volatilisation increased linearly with concentration in the presence of H_2S, so that the percentage of CH_3HgCl volatilised was constant at all concentrations up to 50 μg ml^{-1}, the highest concentration tested. The rate of volatilisation was temperature dependent—at 37 °C about 90% of added alkylmercurial was lost from solution, whereas at 5 °C only 50% was lost.

We attempted to trap and identify the volatile product of the reaction between H_2S and $CH_3{}^{203}HgCl$ or $^{14}CH_3HgCl$ using a solution of sodium carbonate and disodium phosphate[9] (Table 2). Nearly all the evolved radioactivity, whether ^{203}Hg or ^{14}C, was absorbed by the carbonate–phosphate solution. In the absence of H_2S, little radioactivity was lost from solution and virtually none was found in the trap. In experiments described in Table 2 there was considerable variation in the amount of mercury volatilised, probably due to differences in initial H_2S concentration, or slight leakages from the desiccator seals. Consequently the differences between percentage loss of ^{203}Hg- or ^{14}C-labelled methylmercury have no significance, for the experiments were performed on separate occasions.

Table 2 Absorption of volatile mercury compound by carbonate–phosphate solution

Conditions	Radioactivity	% Radioactivity lost from flask	% Absorbed by CO_3/PO_4
H_2S	$CH_3{}^{203}HgCl$	23.3	22.9
	$^{14}CH_3HgCl$	16.3	14.4
Air	$CH_3{}^{203}HgCl$	1.3	0.0
	$^{14}CH_3HgCl$	0.05	0.06

A solution of $CH_3{}^{203}HgCl$ (2 μg ml^{-1}, 0.025 μCi μg^{-1}) or $^{14}CH_3HgCl$ (2 μg ml^{-1}, 0.01 μCi μg^{-1}) in a conical flask was placed in a desiccator which contained in its base a solution of sodium carbonate (10 g l^{-1}) and disodium phosphate (5 g l^{-1}). In two experiments the desiccator was flushed with H_2S for 2 min. After incubation for 3 d at 37 °C, samples were removed from the flask and from the absorber solution to assess the amount of radioactivity volatilised and absorbed.

The identity of the volatile product has not been fully elucidated. It does not seem to be metallic mercury because: (1) both ^{14}C- and ^{203}Hg-labelled volatile products were absorbed to the same extent by the carbonate–phosphate solution, which suggests that the C–Hg bond remains intact, and (2) metallic mercury vapour is not absorbed by the carbonate–phosphate solution which traps only organic mercury compounds[9].

When the radioactive contents of the carbonate–phosphate absorption solution were chromatographed on thin-layer plates of silica gel G-25 (Camlab, Cambridge), using two solvent systems, chloroform–*n*-hexane (9 : 1) (ref. 10), and *n*-hexane–acetone (7 : 3) (ref. 11), the radioactivity remained at the origin. But when the contents of the trap were extracted into toluene, all the radioactivity passed into the toluene phase and the radioactivity then migrated on the thin-layer plates at the same rate as a methylmercuric chloride standard, in the two solvent systems. Thin-layer chromatography of a sample of the radioactivity remaining in the flask revealed that it was CH_3HgCl and that no inorganic mercury was present. Thus, it seems likely that CH_3HgCl and H_2S react to produce a volatile sulphur derivative of methylmercury which, although stable in alkaline solutions, reverts to methylmercury on extraction into a polar solvent.

Fagerström and Jernelöv[12] have suggested that the presence of H_2S in sediments of lakes reduces the rate of methylation of mercury, due to the formation of mercuric sulphide, which is methylated much more slowly than mercuric chloride. The results reported here suggest that H_2S plays a further role in the turnover of mercury in an aquatic environment, that is, that any methylmercury discharged into a lake, or synthesised there by microbial action, may react with H_2S to form a volatile product which is released from the lake, thus making less methylmercury available for accumulation by fish and shellfish.

Mixing in upper layer of a lake during heating cycle

Little is yet known about the structure of the upper 'mixing' layer of the ocean below the zone of direct surface wave influence. We report some measurements of the temperature field in the mixing layer of a freshwater lake during the heating cycle which demonstrate some of the processes which may be important. The temperature field is found to be isotropic at scales less than about 60 cm, but the effect of stratification becomes important at larger

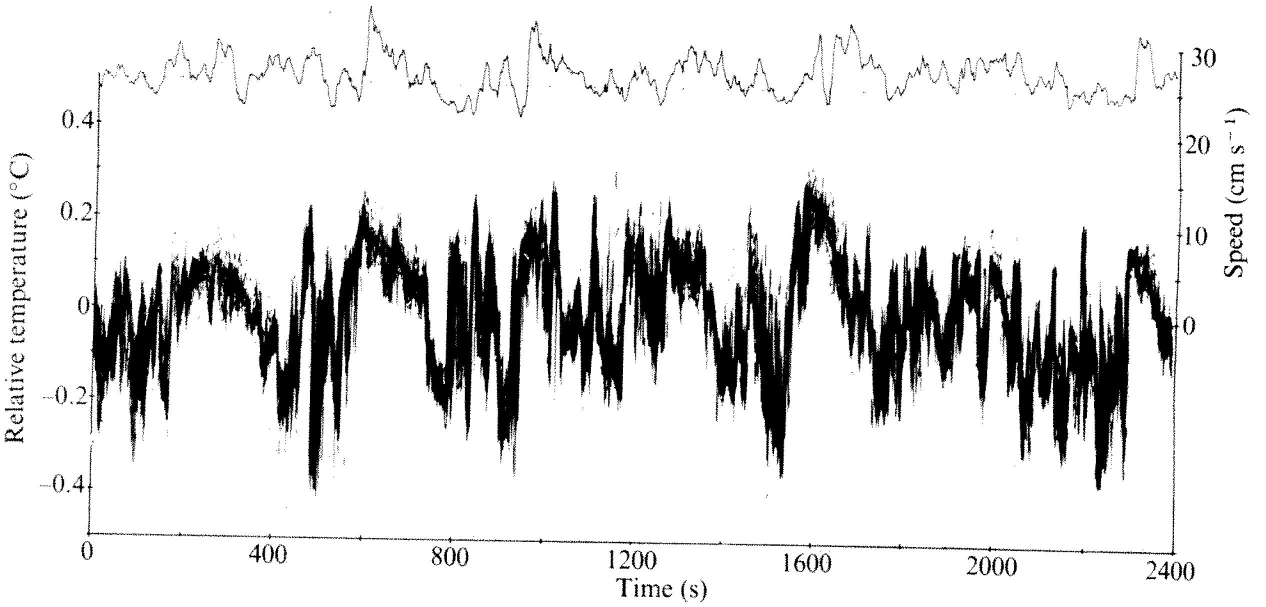

Fig. 1 Temperatures relative to their means and current recorded by the array of thermistors plotted against time. The record starts at 119GMT, July 14, 1976, when the centre of the array was at 6-m depth.

scales, reducing the vertical correlations in comparison with the horizontal. The spatial evolution of structures is dominated by the shear, as appropriate in the low Richardson number region. Examination of the stability of the mean velocity and density profiles shows that Kelvin–Helmholtz instability may be expected, leading to billows with wavelengths of about 60 m, and corresponding to fluctuation scales observed in the temperature records. Similar fluctuations have been seen in the nocturnal atmospheric boundary layer.

The measurements were made with a thermistor array in Loch Ness, 250 m from the north-east shore near Achnahannet, where the water depth is 170 m. The fetch at this site is over 20 km when south-west winds are blowing along the axis of the loch. The array consists of seven thermistors at 25-cm separation on a vertical rod, five at 45-cm separation in the direction of flow (orientation being maintained by a vane on the supporting tube) and three at 45- and 90-cm separation in the horizontal across the direction of flow. The sampling rate is 1 Hz and resolution 0.001 °C. The loch is freshwater, so density can be inferred from the temperature measurements. The array also carries a Savonius rotor current meter, a small vane and compasses to determine the flow direction.

Figure 1 shows the relative temperature values against time. The mean air temperature was about 1.8 °C in excess of the surface water temperature, and the wind speed was 10.6 m s^{-1} from the south-west. The dominant surface wavelength was estimated as 10 m, and whitecapping was frequent. There are fluctuations in temperature with a period of about 6 min and with a vertical scale which exceeds the array dimensions (the coherence between thermistors being high), as well as less coherent rapid fluctuations. The current speed is also shown in the figure and was directed in the wind direction with a variation of less than 20°.

We define the four-dimensional correlation function $C(x, y, z, \tau)$, the cross correlation between thermistors at relative position (x, y, z) at time lag τ by

$$C(x, y, z, \tau) = \frac{\overline{T(x, y, z, \tau + t) \cdot T(0, 0, 0, t)}}{(\overline{T^2(x, y, z, t)} \cdot \overline{T^2(0, 0, 0, t)})^{1/2}}$$

$T(x, y, z, t)$ is the variation of the temperature from its mean value, and is recorded at time t by a thermistor at a position (x, y, z), where x is directed north-east along the loch axis in the wind direction, y is across and z is vertically upwards. The overbars imply means taken with respect to time. Figure 2 shows sections of the constant C surfaces. For thermistor spacing <60 cm the $y = \tau = 0$ correlations in directions x and z are large and almost equal, but for larger scales the correlation in the vertical decreases

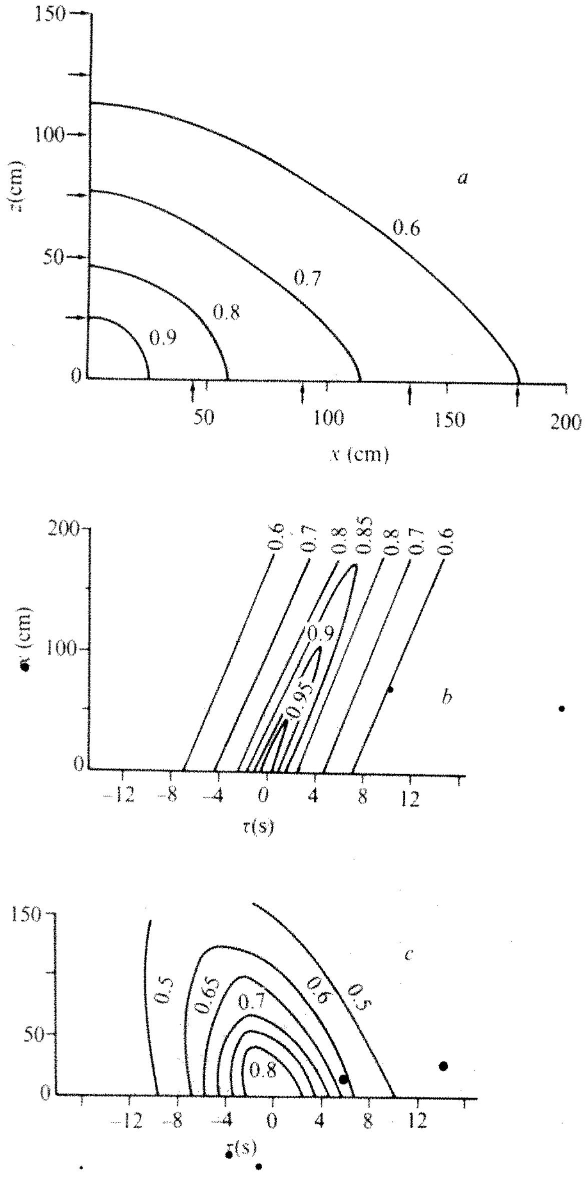

Fig. 2 Sections of the correlation function $C(x, y, z, \tau)$. *a*, Section $y = \tau = 0$. *b*, Section $y = z = 0$. *c*, Section $x = y = 0$.

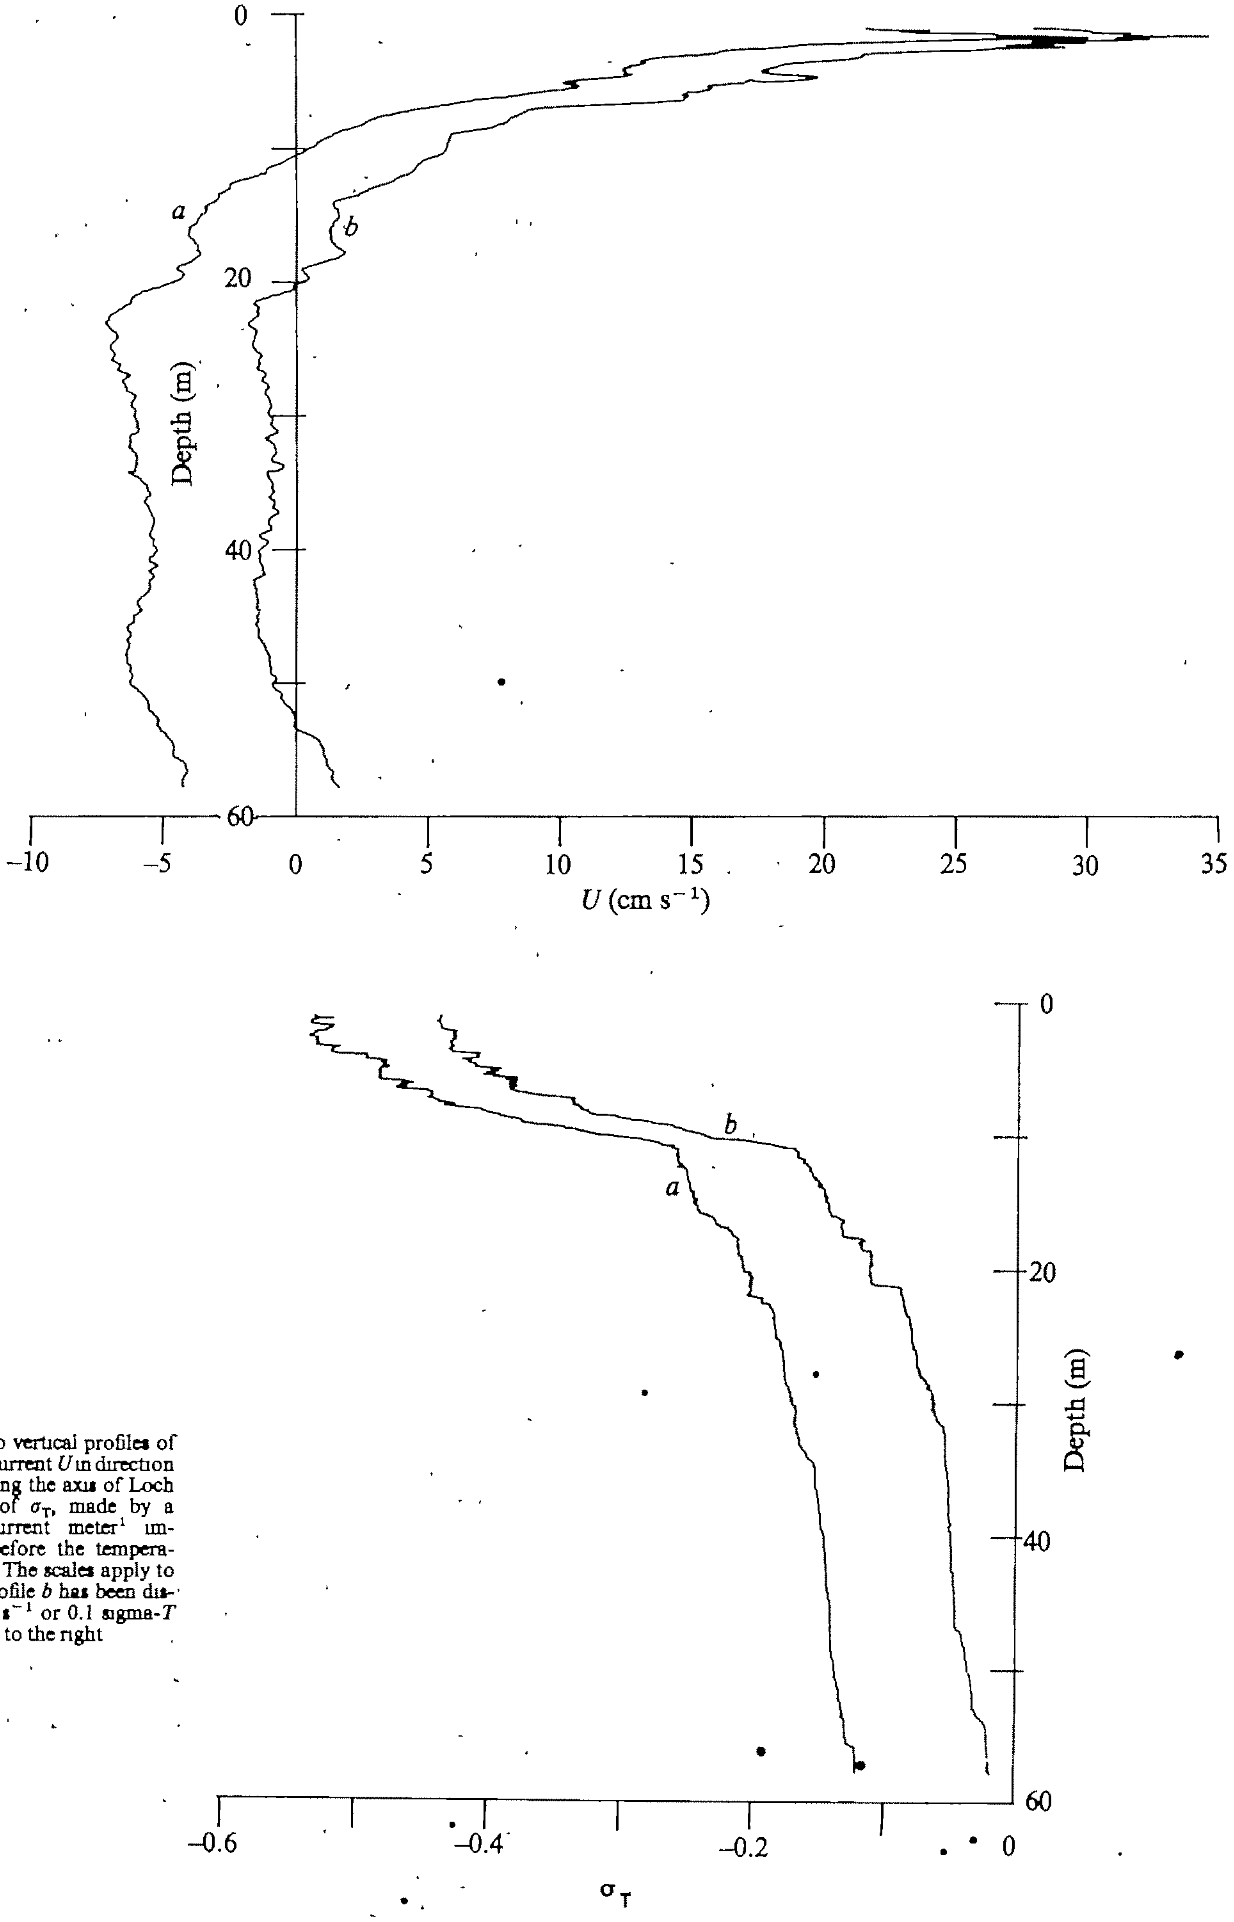

Fig. 3 Two vertical profiles of horizontal current U in direction 036 $\propto$ T along the axis of Loch Ness, and of σ_T, made by a profiling current meter[1] immediately before the temperature record The scales apply to profile *a* Profile *b* has been displaced 5 cm s^{-1} or 0.1 sigma-T units to the right

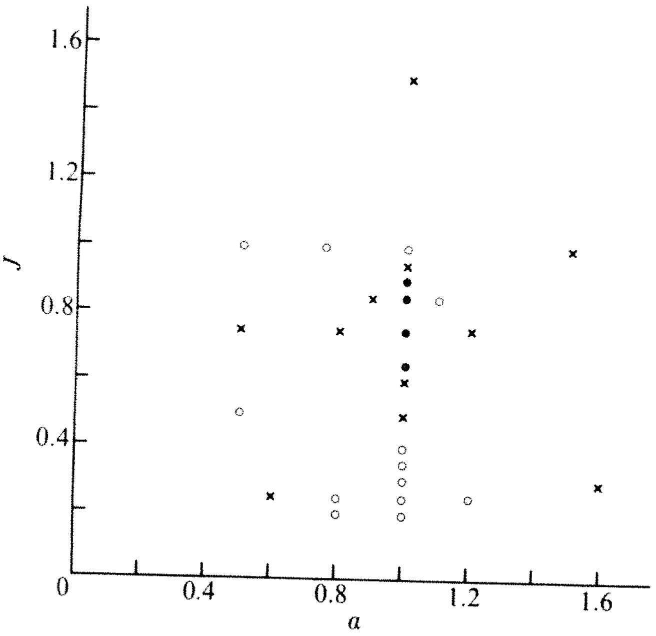

Fig. 4 The wave number, α, and Richardson number, J, plane, showing positions at which stable and unstable waves are found. The wavelength is $20\pi/\alpha$ (m) and the $J = 1$ corresponds to the observed mean profile. ×, stable waves; ○, waves which are unstable but have e-folding growth time exceeding 1 h; ●, unstable waves with shorter growth times.

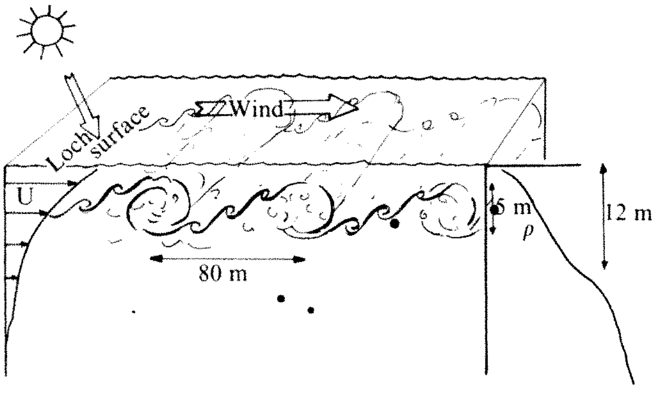
more rapidly than in the horizontal, the ratio of horizontal to vertical scales at which $C = 0.6$ is reached being 1.59. The tilt of the constant C contours in the x–τ surface indicates the downstream advection of coherent structures through the array at a velocity which is, within the accuracy of the measurement, the same as the flow velocity. If the contours were all parallel, the correlation pattern would not change in time as it is advected past the array and the temperature field would be 'frozen' (the Taylor hypothesis). Figure 2*b* indicates that C decreases to 0.85 at $\tau = 7$ s as the pattern is advected and so, by linear extrapolation, $C = 0.6$ at about 19 s, and this is the evolution time scale of the temperature field. Figure 2*c* shows that the C contours in the z plane are also slightly skewed, indicating a downward propagation of coherent structures. No evidence of horizontal anisotropy was found in the analysis of the y correlations.

Figure 3 shows two profiles of current U and σ_t. The layers above 10 m are subject to a strong shear and contain frequent inversions in which the density decreases with depth. These have a r.m.s. scale of 76 cm, corresponding approximately to the scale at which the vertical coherence falls to about 0.7 and the anisotropy is first found between the vertical and horizontal structures. The Brunt–Väisälä period in this upper layer is about 600 s, so that the evolution scale of the thermal structures is not consistent with their being internal waves, which should have longer periods. The time scale of vertical shear, $(du/dz)^{-1}$, is, however, about 25 s and is comparable with the evolution scale. The apparent downward propagation of coherent thermal structures is consistent with the stretching of symmetrical structures in the mean flow. After the evolution time t, an initially vertical structure would have an inclination of $\tan^{-1}[(t\,du/dz)^{-1}]$ or 53° and this is consistent with the tilt and direction of tilt of the contours in Fig. 2*c*. During the process of distortion of such a symmetrical structure by shear the x correlations are unchanged, but the z correlations are reduced by a factor $1/(1 + t\,du/dz)$, giving a ratio of scales, $1 + t\,du/dz$, of 1.76. The estimates of tilt and ratio scales are affected by the choice of $C = 0.6$, but show reasonable agreement with observations, indicating a shear-dominated structure at the 1-m scale.

Fig. 5 A schematic diagram of the billows. The vertical scale is inferred from the mean vertical profiles and the magnitude of the temperature fluctuations measured by the array.



The equation which governs the growth of small disturbances to a parallel shear flow in a stably stratified fluid is the Taylor–Goldstein equation[2]. This has been solved numerically[3] for given wave numbers, α, and Richardson number, J, using values of U, the horizontal current along the loch axis, and N, the Brunt–Väisälä frequency, obtained from 1-m vertical averages of the profiles (Fig. 3), with linear interpolation between the lowest measured values and the bottom of the loch. Figure 4 shows the conclusions. The largest growth rate is found at $J = 0.9$, $\alpha = 1.0$, corresponding to a wave of length 63 m moving with a speed which increases its amplitude exponentially in a time of 22.4 min. This wave requires a Richardson number only 10% less than that observed, that is an increased mean shear of only 5%. These waves would have their orientation across the wind and current direction (Fig. 5), and may account for the longer period fluctuations in temperature seen in Fig. 1. Inversions occurred most frequently in the regions of large rapid fluctuations (e.g. near 100, 500 and 900 s), and these appear to be the locations of the overturning billows. Similar waves have been observed using radar in the stable nocturnal atmospheric boundary layer over land[4,5], and may provide an important vertical diffusion process in stable boundary layer flows.

The age and extent of the Red Sea oceanic crust

THE evolution of the Red Sea depression and the extent within it of oceanic crust have been widely discussed[1–5]. It is generally accepted that the axial trough is floored by oceanic lithosphere formed at a constructive margin over the last 3–4 Myr by spreading at a rate of about 1.0 cm yr^{-1} per flank[2,6]. It is also clear from stratigraphic continuity and the trend of isofacial lines that the opening of the Red Sea started less than 45 Myr ago after a long period of tectonic and magmatic quiesence[7,8]. Two areas of contention exist. First, how much of the Red Sea on either side of the axial trough is underlain by oceanic crust, and second, when was this oceanic crust formed?

The sedimentary record shows that before the Middle Oligocene (32 Myr) a shallow sea extended southwards from the main 'Tethyan Ocean' on to the then contiguous Nubian–Arabian plate[8,9]. South of this sea was a low-lying flat or gently warped peneplaned land surface[8]. A drastic change occurred in the Red Sea at the beginning of the

Miocene (about 26 Myr). Evaporites began to be precipitated and these, by the end of the period (7 Myr), had attained thicknesses of 4–5 km. Also, coarse clastic sediments first appear as marginal intercalations within the evaporites[10,11]. It is obvious that from that time (27 Myr) uplift occurred periodically along the sides of the Red Sea, which was attaining something near its present shape and extent. So, uplift and the formation of the Red Sea linear depression seem to have started about 26 Myr ago. At about 30 Myr ago the eruption of 50,000 km^3 of trap basalts in Ethiopia and south-west Arabia started[4,7] although localised, minor activity had occurred before that time[12]. Both volcanism and uplift were active during the last 30 Myr although the main trap volcanism seems to have stopped by 24 Myr (ref. 13) before the major uplift took place[4]. Investigations in Afar[14–16] have established the alternating nature of vertical movements and volcanism; when there was volcanism there was little or no uplift and vice versa. In the Afar the processes started about 25 Myr ago[14] and have continued ever since with a cyclic periodicity of 2–4 Myr (ref. 16). Further investigation of the eastern Red Sea coast in southern Saudi Arabia[4] convincingly demonstrate the presence of a 22-Myr old linear volcanic zone in which dyke injection is related to crustal thinning and warping and the development of the Red Sea depression in that area.

Are the geophysical data compatible with this primarily geological scenario? There is no geological objection to the conclusion, based on seismic refraction[3] and magnetic anomaly[6,19] studies, that the Miocene evaporites which flank the axial trough are underlain by oceanic crust, although it could be argued that the sub-evaporite P-wave velocities of 6.6 km s^{-1} (ref. 3) are more characteristic of coarse-grained basic rocks of layer 3 than the finer-grained extrusives of layer 2. It is also geologically acceptable that the linear magnetic anomalies over the evaporites are oceanic strip anomalies whose amplitude has been reduced by the thick sedimentary overburden. Further, the near coast-to-coast fit of the Arabian plate to that of Nubia, based on plate tectonic theory, is in keeping with these data[5,20].

Girdler and Styles[6,19] compared the anomaly profiles from an evaporite-covered area on the west side of the axial trough between 15° and 16°N with the magnetic anomaly reversal timescale. They conclude, on the basis of the best anomaly profile match, that the oceanic crust beneath these evaporites was formed either 41–34 Myr ago with a spreading rate of 1.3 cm yr^{-1} per flank or between 29 and 24 Myr ago with a 2.3 cm yr^{-1} spreading rate. They preferred the older period as the profile match was better and the spreading rate more plausible. It is geologically difficult to accept the older period as this requires that crustal downwarp, transcontinental rifting and the formation of over three-quarters of the Red Sea oceanic crust occurred at a time when there is no geological evidence of major uplift, magmatism and crustal deformation anywhere in the region. The younger period (29–24 Myr) would indeed coincide with an episode of intense magmatic and tectonic activity, but it still leaves 20 Myr (24−4) in which it is supposed that no spreading occurred under the Red Sea, whereas magmatic activity and large scale vertical and horizontal movements occurred around the periphery.

The model that best fits the geological data is a Red Sea linear depression that formed in the late Oligocene–early Miocene (25–26 Myr), with sea-floor spreading continuing intermittently ever since. I attempt here to determine whether the magnetic data can be fitted into this model. The problems arise from the evaporites. They are, on all accounts, of Miocene age and are primarily composed of halite with minor anhydrite, shale and marl horizons. Invoking the law of superposition, if the evaporites are Miocene (26–27 Myr), then whatever is underneath must be pre-Miocene—older than 25 Myr. But must it? Evidence that this is not necessarily so comes from Girdler and Whitmarch[21] who describe DSDP sites 227 and 228 at the edge of the axial trough. Here, Miocene evaporites overlie oceanic crust confidently identified as aged less than 2.5 Myr on the correlation of the well-developed linear magnetic anomalies of the axial trough with the reversal time scale. They convincingly demonstrated that, as most of the evaporite is rock salt at temperatures above 100 °C at the base of the sequence, flow is not only possible but likely, and this is confirmed by petrographic studies (Shearman, personal communication). If Miocene evaporites have flowed over the recently formed axial trough oceanic crust, could not such flow have occurred throughout the development of the Red Sea? Recent volcanological[22] and ocean-floor studies[23] indicate that sea-floor spreading can be intermittent on a relatively short time-scale. It would be consistent with the Afar evidence and the cyclic occurrence of coarse clastic sediments within the marginal evaporites, if spreading along the Red Sea constructive margin had taken place intermittently over the last 25–30 Myr. If the spreading phase continued long enough and was fast enough, the overlying evaporites would part and an axial trough form, only to be obliterated by salt flow when spreading stopped. Conversely, if the constructive margin processes were slow and short-lived, then oceanic lithosphere would be produced beneath an evaporite cover; a locale far more likely to form coarse-grained basic rocks with a characteristic 6.6-km s^{-1} P-wave velocity[3].

There are two possible objections to this model. First, of the 105 km of post-Cretaceous sinistral movement along the Jordan rift[24], only 40–45 km can be proven to be of post-Lower Miocene age. Yet Freund *et al.*[24] claim that this 40–45 km of latest movement probably took place in the last 12–7 Myr and, accepting an average movement rate of between 0.4 and 0.6 cm yr^{-1} for the entire 105 km, they calculate that movement along the rift began 20–30 Myr ago (ref. 24, p. 124)—dates entirely in keeping with the proposals made here. Second, the ages of 36 and 30 Myr for a mildly metamorphosed argillite and basalt[25] at the bottom of two boreholes into the evaporites are quoted by Girdler and Styles[6,19] in support of the 41–34 Myr spreading phase. But, as well as the dubious validity of stratigraphically uncontrolled whole rock K–Ar age determinations, Lowell and Genik identify a continental setting for both the argillite and the basalt (ref. 25, p 249). It seems therefore that the proposal for a 41–34 Myr spreading phase must stand on magnetic anomaly matching alone. The veracity of this procedure for the Red Sea must be queried, for it produces results that conflict with the majority of other evidence.

I thank P. W. Francis, R. M. Shackleton, P. J. Smith and S. A. Smith for discussions.

Andesitic pyroclastic flows from Colima Volcano

COLIMA (19°31′N, 103°37′W) is important as one of the most continuously active continental andesite volcanoes in North America. Various types of pyroclastic and lava eruptions have been reported over the last 400 yr (ref. 1). Here we describe the eruption of andesitic lava and associated pyroclastic flows during December 1975–April 1976. On the basis of our visits between January and June, 1976, we comment on the relationship of this to earlier eruptions of Colima.

Colima is a large composite volcano, now slightly over 4,000 m high, situated within a caldera[1] (5 km diameter) on the southern flank of the extinct Pleistocene volcano of Nevada de Colima (4,320 m, rising from a base level of 1,500 m). Colima forms part of the Mexican Volcanic Belt, which is associated with subduction of the oceanic Cocos plate below continental Mexico[2]. Eruptions of Colima have been noted since 1576 and to view the 1975–76 eruption in perspective we summarise the history during the present century.

In 1906, the volcano had a conical form,[1] with truncated summit and a small crater. A large explosive eruption in 1913 produced an extensive airfall deposit and 'nuée ardentes'[3–4], and left a much larger crater with a rim height of 3,960 m (ref. 4). Growth of a lava dome within the crater during 1913–35 was accompanied by mild explosive activity, and by 1935 the dome was 60 m below the crater rim. The volcano was quiescent until 1958, when the dome began to rise again so that its highest parts reached the level of the crater rim. This led to extrusion of a blocky andesite flow from the side of the dome down a prominent gully on the northern flank of the cone during 1961–62 (ref. 5; Fig. 1). Since 1962 the dome has grown slowly so that the volcano's height increased to an estimated 4,100 m by 1975, before the start of the latest eruption.

The eruption started on December 11–12 with mildly explosive activity, the extrusion of andesite lava in three small lobes to the north and two flows down the south-east flank of the cone (Fig. 1). Extrusion of the lobes was completed rapidly, probably within a few days, and they were static on January 3. On that date the east–south-east flow was moving very slowly but the most south-easterly flow was very active and continued to flow until studied in detail on January 14–15. In contrast with the lobes to the north of the cone, and the older 1961–62 flow, both south-easterly flows have prominent levées.

A variety of pyroclastic and rock deposits, below the north lobes and on the western side of the volcano below the summit dome, are associated with the early phase of the eruption. These include 'hot avalanche' deposits[6] erupted during lava or dome growth on a steep slope, colder avalanche deposits formed during cooling and disintegration of lava, and more slowly accreted rock-fall debris. During part of the early phase, juvenile andesite blocks up to 0.5 m³ were ejected explosively, falling up to 2 km from the cone.

Between January 3 and 15 there was strong fumarole activity from depressions in the summit dome (Fig. 1); occasional colder rock-falls, and active lava flow movement only on the most south-easterly flow. The lava flowed down the Barranca de la Arena (Fig. 1) and reached 2 km from the cone by January 14–15, when it was examined in detail at the point indicated on Fig. 1. At this time andesite lava was flowing down the barranca over a break of slope 50 m high. Flow of lava down the valley was accompanied by pyroclastic flows ranging from hot avalanches to a nuée ardente type of flow. The hot avalanches comprised large falls of hot (often flowing) rocks with total volumes up to 10 m³. The falls were from the steep, 40-m front face of the lava flow. The slope below this face was about 40°; this slope representing a steep section of the barranca, smeared with lava debris. The avalanches generally travelled up to 100 m down the valley and recurred every 4–5 min.

All gradations occurred between the hot avalanches and a pyroclastic flow resembling a small nuée ardente. The latter flow was initiated by the collapse of a substantial mass of hot (often glowing) blocks from the lava flow front. These were immediately engulfed in an expanding dusty cloud. After formation, the flow moved away from the lava front quietly (in great contrast to hot avalanches). The cloud expanded simultaneously in all directions away from the flow, eventually engulfing a considerable area (hundreds of m²) of the surrounding countryside and leaving a deposit of very fine brown dust. The cloud had cooled before engulfing the observation point, 200 m from the flow front.

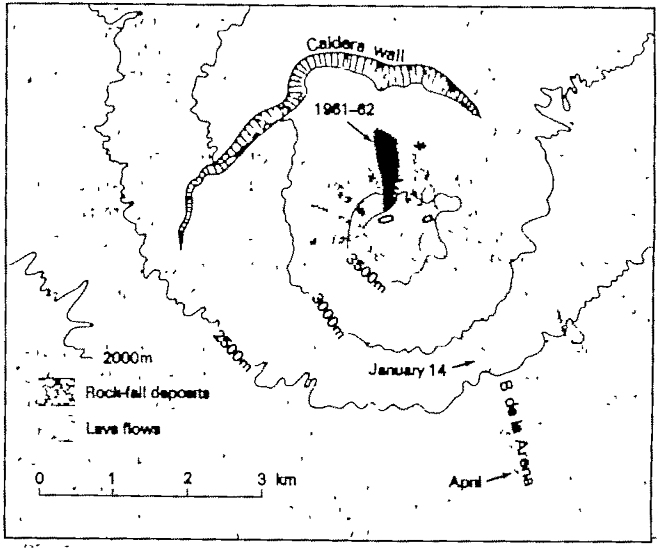

Fig. 1 Map of Colima volcano, showing lava and rock fall (including pyroclastic deposits) formed during the 1975–76 eruption. The outlined area labelled, 1961–62, extending to the north of the summit, is the lava flow erupted during these years. Solid lines on the summit enclose depressions in the lava dome which have abundant fumaroles.

We believe that the quietness of the pyroclastic flows is significant since it must indicate movement of blocks as a suspension within the flow. Arrest of the flow was accompanied by resumption of considerable noise, and blocks were deposited from the flow. The pyroclastic flows were also characterised by a narrow channel, a few m wide, in the underlying rock deposits. This was partly erosional in character but also reflected alignment of the deposited material. Such pyroclastic flows were formed every 7–8 min during the period, the earlier passage of flows down the same valley being indicated by destruction of trees at the top of the valley walls—the trees having been aligned down-valley. Between January 15 and April the lava flowed a further 1–2 km (Fig. 1) and movement ceased on June 20.

This type of pyroclastic flow has been reported from several volcanic areas, including Indonesia and central America (for example, Santiaguito, Guatemala[10]), and is similar to flows erupted at Merapi (Java) as a result of collapse of the side of a growing lava dome[7,8]. They have been termed 'Merapi-type' pyroclastic flows[8]. The pyroclastic flows were a common and characteristic part of the 1975–76 eruption of Colima, and we infer that they grade upwards in scale to larger nuée ardentes described from earlier eruptions of Colima and possibly formed at an earlier stage of the 1975–76 eruption. It seems likely that deposits from these eruptions would be difficult to identify with confidence in an older mixed succession of lavas and pyroclastics. We therefore suggest that such pyroclastic flows are more important than commonly supposed in the growth of composite andesite volcanoes. Although it is difficult to estimate, our study of Colima suggests that as much as a third of the erupted products of this volcano might be deposits from pyroclastic flows of the types described here.

Our studies of Colima were made during a visit sponsored by Earthwatch (Educational Expeditions International) and the Centre for Field Research (Belmont, Mass.). We thank the expedition participants for help in making the observations, E. Areola and L Flores for assistance in Cuidad Guzman and on Colima, and many friends in Mexico for help and encouragement.

Detection of atmospheric infrasound by homing pigeons

ACOUSTIC waves of frequencies below 10 Hz are common in the atmosphere. They are generated by various sources, including wind, thunderstorms, weather fronts, magnetic storms, aurorae, ocean waves, earthquakes, and many of man's mechanical devices[1–3]. Many of these atmospheric oscillations are of high amplitudes (frequently well above 100 dB SPL at frequencies below 5 Hz, and above 120 dB below 1 Hz) but because they are outside the normal limits of human hearing they usually go unnoticed (although humans can detect extremely loud artificial infrasounds generated in test chambers, these sounds are louder than most natural infrasounds and verge on the threshold for pain)[4,5]. It has been suggested, however, that migrating and homing birds might make use of the cues provided by such infrasounds[6]. During our ongoing study of the sensory basis of avian orientation, we investigated this possibility. We report here that homing pigeons (*Columba livia*) are sensitive to infrasounds at reasonable amplitudes.

Our testing procedure, using a conditioned cardiac response (increased rate of beating), was very similar to one used to test for sensitivity to barometric pressure changes[7]. The pigeon was fitted with two ECG surface electrodes and two shock electrodes (implanted under the skin of the breast), restrained by a leather harness, and placed in a sound-insulated conditioning chamber 30×44.5×30 cm high (the chamber was described more fully in the barometric pressure study[7]). Fresh air for respiration was supplied at 5 l min^{-1} through a system of pressure and vacuum pumps; however, this input was cut off and the chamber completely sealed for short periods while tests at very low frequencies were run (this reduced the background noise in the chamber by about 20 dB).

Two methods of producing acoustic pressure oscillations were used. In some of the early tests, we used a motor-driven piston of approximately 1 cm diameter, with an adjustable stroke to produce changes in amplitude. This apparatus was modified from a Phipps and Bird small animal respiration pump, model 70-878-01. The pressure output was a sine wave and the frequency was varied by changing the motor speed. The piston was always stopped at the mid-point in the cycle, insuring that the next stimulus would start at zero amplitude. In later experiments, the pressure variations were produced by a loudspeaker driver (Atlas sound PD-60-T) connected to the chamber with tubing so as to act on a closed volume of air. In such a closed system, the loudspeaker driver was not limited to the normal free-air frequency response, but instead could produce low-frequency pressure changes in the chamber well below 0 1 Hz. The loudspeaker driver was powered by a Hewlett-Packard sine wave generator, model 200 C. With both methods of producing pressure changes, the sounds were piped through approximately 2 m of plastic tubing 1 cm in diameter and passed through a mechanical lowpass filter before entering the chamber. The filter served to reduce high-frequency sounds in the audible portion of the spectrum. The lowpass filter was constructed of a cylinder 5 cm in diameter and 15 cm long, coaxial with the 1 cm tubing and packed with glass wool. The frequency characteristics of the filter will be described in detail elsewhere. The rise and fall times of the stimulus envelope were controlled to virtually eliminate high-frequency transients.

Stimulus presentations were at random intervals. Before each presentation, the heart rate of the pigeon was monitored for 5 s; this was followed by a 10 s stimulus, which was in turn followed immediately by a shock (1 mA for 350 ms from a 60 Hz a c. constant-current source). After a few trials, a conditioned response developed, and the heart rate increased each time the bird detected the stimulus, before the shock. For a positive response to be counted, the heart rate during the 10 s stimulus period must have exceeded by at least 12 beats per min the highest rate recorded during the preceding 5-s baseline period. Typical baseline rates were approximately 140 beats per min, and accelerations in response to stimuli ranged from 30 to 60 beats per min. Instantaneous heart rate was monitored with a Grass Instrument 7P4 tachograph, with a linear voltage output proportional to heart rate, measured on a beat-to-beat basis. A permanent record of the heart-beat rate was made on a Sanborn 350 chart-recorder.

Our experiments demonstrate that homing pigeons can detect sound energy below 10 Hz at amplitudes well within the range of naturally occurring sounds at these frequencies. Indeed, they can detect frequencies below 1 Hz. At 113.8 dB r.m.s. SPL (1 mm H$_2$O), most birds responded to stimuli of 1.67 Hz and 0.8 Hz at a much higher rate than background

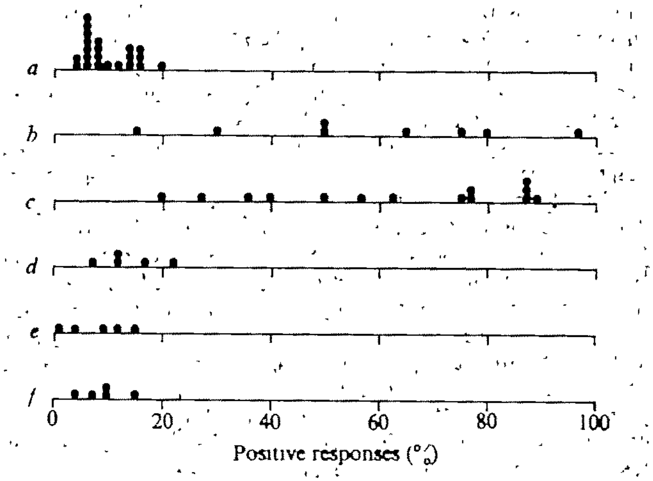

Fig. 1 Percentage of positive responses of individual homing pigeons to infrasound stimuli (40 presentations each). *a*, Chance 'positive' response levels of 22 birds when no stimulus was provided; this is the background level against which responses in other test situations should be evaluated. *b*, Responses of eight pigeons to sounds of 1.67 Hz. *c*, Responses of 14 pigeons to sounds of 0.8 Hz. *d*, Responses of five pigeons to sounds of 1.67 Hz when the tubing between the sound generator and the test chamber was closed by pinch clamps. *e*, Responses to sounds of 1.67 Hz by five pigeons whose cochleas and lagenas had been removed. *f*, Responses to sounds of 1.67 Hz by five pigeons whose columellas had been bisected. All sound amplitudes were 113.8 dB rms SPL.

(compare Fig. 1*b* and *c* with 1*a*). The response could be eliminated if two pinch clamps were placed on the tubing between the sound generator and the test chamber (Fig. 1*d*).

From preliminary experiments, we estimate the threshold (50% response) to be approximately 80 dB at 1.5 Hz, 60 dB at 5 Hz, and 50 dB at 10 Hz. These compare with published values for human thresholds of 132 dB at 1.5 Hz, 115 dB at 5 Hz and 104 dB at 10 Hz (ref. 5). The ambient noise levels inside the insulated chamber were 70 dB at 1.5 Hz (band width (bw) 10% of centre frequency), 50 dB at 5 Hz (bw 1%) and 47 dB at 10 Hz (bw 1%); inasmuch as the 50% threshold values were only slightly above these noise levels, it seems possible that the pigeons would be even more sensitive to signals of these frequencies if tested in a quieter chamber. (A more detailed study of threshold response values, down to 0.1 Hz, is in progress.)

To determine the location of the receptors responsible for infrasound detection, we tested five pigeons from which the cochleas (and lagenas) had been surgically removed, and also five pigeons with intact cochleas but with both columellas bisected so that there was no direct conduction of sound between the tympanum and the oval window. Figures 1*e* and *f* show that neither of these groups of birds respond to an infrasound stimulus of 1.67 Hz at 113.8 dB; the response levels for both groups were indistinguishable from those of normal birds in the absence of a stimulus. These results suggest that the receptors for infrasound are in the inner ear, but it is not clear which organ is responsible because removal of the cochleas and lagenas unavoidably damages the remaining portions of the labyrinth, one part of which has recently been shown to function (at least in frogs) as an auditory receptor[8].

Unlike sounds easily audible to humans, atmospheric infrasounds can travel huge distances—often thousands of miles—without much attenuation (which is proportional to the square of the frequency). Hence such sounds could potentially provide birds with much useful information. For example, the ability of birds to sense approaching weather fronts might be aided by detection of infrasounds funnelled to earth by those fronts or by detection of the infrasound components of thunder associated with storms that are still hundreds of miles away. Localisation of several remote infrasound sources could serve as a distant landmark system for triangulation of the home site and of the location of a release site. Properly utilised, infrasound information could thus assist in almost every aspect of avian navigation, in both homing and migration.

Whether one or more of these potential uses is actually realised is not known. There are several reasons why birds might have difficulty extracting meaningful information from infrasounds. For example, they would need to distinguish between spatially coherent infrasounds and so-called pseudosounds, which are very local pressure oscillations generated by winds and atmospheric turbulence. Further, the usual binaural comparison methods of localising sounds would be ineffective where the wavelengths are so very long (approximately 300 m for a sound of 1 Hz). Neither of these problems should be insurmountable for a bird in flight. Thus a flying bird might be able to reconstruct the spatial patterns of atmospheric infrasounds and thereby separate them from local pseudosounds. Quine and Konishi[9] have shown that, in the usual audible range, owls can distinguish frequencies that differ by as little as 0.5–0.7%; if such discrimination holds for pigeons in the infrasound range, then doppler shifts in frequency, which for a pigeon flying at 20 m s^{-1} toward or away from the sound source would be as high as 14%, could provide ample information for localisation. Only further research can reveal whether or not this is mere speculation.

We thank Dr Douglas Paine of Cornell University for pointing out the potential of infrasound as a source of environmental information. We are also grateful to Dr Geoffrey A. Manley of McGill University for performing the surgery (removing the cochleas and bisecting columellas). This research was supported by grants from the US NSF.

Genetic influences and infantile autism

IN his original description of infantile autism, Kanner suggested an "inborn defect", because symptoms were often present from early infancy. Despite the rarity of a family history of autism and lack of a known increase in parental consanguinity, there are two reasons for suspecting hereditary influences: the 2% rate of autism in siblings is 50 times that of the general population[1], and a family history of speech delay is found in about a quarter of families[2]. Reports of single pairs of twins with autism have not added much to our knowledge of genetic effects because of a bias toward reporting monozygotic (MZ) concordant pairs and because few reports contain both adequate clinical descriptions and evidence of zygosity[1]. We therefore undertook a study of a systematically collected sample of 21 pairs of same-sexed twins, one or both of whom had autism as diagnosed by the criteria of Kanner[3] and Rutter[4]. The results reported here indicate the importance of hereditary influences in the aetiology of autism.

The names of twins were collected from consultants, schools and units for autistic children, the National Society for Autistic Children and two hospital twin registers. Apart from two pairs in which dermatoglyphics were used, zygosity was determined by blood grouping in all cases not markedly different in physical appearance. Case notes of the 33 pairs thus obtained were reviewed and eight pairs were rejected on diagnostic grounds. The remaining 25 pairs and their families were extensively interviewed, tested and examined at home or in hospital. Obstetric records and case notes were also studied. On the basis of all information, a further four pairs were excluded as not meeting diagnostic criteria.

The adequacy of our sampling is shown by the MZ: DZ ratio (11 : 10) which was about that expected for same-sexed twin pairs surviving the first year (6 : 7); and by the number of autistic twin pairs found. In the English twin population of school age who would meet our diagnostic criteria, between 19 and 27 autistic children would be expected and 20 were found. Our sampling of children over school age was less complete, but not likely to be biased as to zygosity or concordance since most cases came from twin registers.

The diagnoses were made from case summaries, numbered randomly to prevent sorting by pair, and from which name, exact age, and zygosity had been deleted.

At least one member of 21 same-sexed pairs of twins met the diagnostic criteria for autism. In all, the 11 MZ and 10 DZ pairs gave rise to 25 autistic children. Apart from being twins, these were similar to other reported series of autistic children with respect to sex ratio (3.4 : 1), social class (57% from I and II), and IQ (about 1/2 severely retarded but 1/4 with normal non-verbal IQ). Affective disorder was described in four families, but schizophrenia did not occur. One sibling suffered from autism (a rate of 2.8%). Delayed speech was reported in three families (Table 1).

Four of the 11 MZ pairs but none of the 10 DZ pairs were concordant for autism ($P=0.055$). All concordant pairs were male. Because autism is a rare condition (about 4 per 10,000 children), the MZ concordance rate is equivalent to a very high correlation in liability (over 0.9) using the multifactorial model[8,9].

If, using this model, it is hypothesised that autism reflects some form of continuously distributed, abnormal characteristic, the question arises whether the non-autistic co-twins showed any other abnormality. We found that very few did in the DZ pairs but in most MZ pairs the co-twins showed some form of cognitive disorder (see Tables 1 and 2).

Table 1 Pair-wise concordance by zygosity

	MZ pairs ($n = 11$)	DZ pairs ($n = 10$)	MZ–DZ difference (exact test)
Concordance for autism	36%	0%	$P = 0.055$
Concordance for cognitive disorder (including autism)	82%	10%	$P = 0.0015$

Thus, in addition to the autistic twins, 6 non-autistic co-twins (5 MZ and 1 DZ) showed a cognitive abnormality as defined by the criteria of no phrase speech until 3 yr (three cases), IQ 70 or below (two cases), severely abnormal articulation after 5 yr (two cases), or scholastic difficulties requiring special schooling (two cases). Four non-autistic twins showed only one of the above features and none were severely handicapped. All the autistic twins met at least two of the criteria. Thus, 9 (82%) of the 11 MZ pairs were concordant for cognitive disorder/autism compared with only 1 (10%) of the DZ pairs ($P=0.0015$). The findings strengthen the suggestion of genetic determination and indicate that what is inherited is a form of cognitive abnormality which includes but is not restricted to autism.

Table 2 Summary of findings for MZ pairs

	First-born twin	Second-born twin
1	Autism + severe MR	Autism + severe MR
2	Autism + mild MR	Autism
3	Autism + severe MR	Autism + severe MR
4	Autism	Autism + mild MR
5	Mild MR	Autism + severe MR
6	Autism	Educational difficulties (ESN school)
7	Severe articulation defect	Autism
8	Autism + severe MR	Language disorder
9	Mild MR	Autism + severe MR
10	Autism + mild MR	Normal
11	Normal	Autism

MR, Mental retardation.
ESN, Educationally subnormal.

Twins have a raised rate of perinatal difficulties leading to brain injury and it was necessary to check that the concordance was not an artefact of these. We found that it was not. In none of the four pairs concordant for autism did both twins have a history of brain injury. Furthermore, no twin with cognitive disorder in the absence of autism showed evidence of perinatal brain injury (Table 3).

Brain injury was, however, relevant to discordance

Table 3 Summary of biological hazards in discordant pairs

Hazard	Autistic twin	Non-autistic twin
	MZ pairs	
Definite	Multiple congenital anomalies	—
	Neonatal convulsions	—
Possible	Severe febrile illness	—
	Pathologically narrow cord	—
None	—	—
	—	—
	—	—
	DZ pairs	
Definite	Apnoea	—
	Delay second birth	—
	Delay second birth	—
	Delay second birth	—
Possible or Difference in severity	Severe haemolytic disease + apnoea	Delay second birth
	Severe haemolytic disease + apnoea	Mild haemolytic disease
	Birth weight 1 and ¼ pounds lower	—
	Birth weight 1 and ¼ pounds lower	—
None	—	—
	—	—

regarding autism. We identified five features known to be associated with brain injury: kernicterus, perinatal apnoea of more than 6 min, neonatal convulsions, multiple congenital anomolies, and a second birth delayed by at least 30 min. In 6 of the 17 pairs discordant for autism, the autistic child but not the non-autistic co-twin had experienced one or more of these biological hazards in the perinatal period.

A wider definition of biological hazard was then applied to the 11 cases not differentiated on the stricter criteria. Using the wider definition (lower birth weight by 1 pound or more, pathological narrow umbilical cord, a more severe kernicterus with apnoea and a severe febrile illness—possibly encephalitis–just before onset), a further six discordant pairs were differentiated. Thus, in 12 of 17 pairs discordant for autism, the autistic member probably or possibly suffered a brain injury, whereas in none of the discordant pairs did this occur only in the non-autistic member.

To summarise the results: the markedly higher rate of concordance in MZ, compared with DZ, pairs for both autism and cognitive abnormalities indicates the importance of genetic factors in the aetiology of autism. Indeed, the concordance rates in conjunction with the very low prevalence of autism in the general population point to a strong genetic determination. Nevertheless, the finding of an association between biological hazards in the perinatal period and autism also demonstrates the important role of environmental influences for the causation of autism (but not cognitive disorder).

In some cases, genetic factors seem to be both necessary and sufficient causes. Among the eight autistic children in the four concordant MZ pairs, biological hazards (even using the broader criteria) occurred in only one child. He was more severely affected than his twin. On the other hand, brain injury alone seems to be a sufficient cause in some cases. In one of the two completely discordant MZ pairs, the autistic twin had experienced neonatal convulsions, whereas the non-injured co-twin was normal in every way. The importance of brain damage is also indicated by the finding in other studies of autism in children with congenital rubella or infantile spasms.

Finally, some cases seem to result from the combination of an inherited cognitive defect plus brain damage. In three of the five MZ pairs discordant for autism but concordant for cognitive deficit, the autistic child had experienced a biological hazard whereas the cognitively impaired non-autistic co-twin had not.

Determining the mode of inheritance is difficult since autistic children rarely reproduce. It would be helpful to know what happens to the offspring of the non-autistic twins with cognitive impairment, but no such information is available.

In summary, we conclude that this systematic study of 21 same-sexed twin pairs in which at least one twin showed the syndrome of infantile autism, indicates the importance of a genetic factor in the aetiology of autism. It also indicates the importance of brain injuries, especially during the perinatal period, which may operate either by themselves or in combination with a genetic predisposition involving language. Both the mode of inheritance and exactly what is inherited remain uncertain.

We thank our many colleagues whose collaboration made the study possible.

Anti-fouling role of antibiotics produced by marine algae and bryozoans

A GRADIENT of antibacterial activity along fronds of the large brown seaweed *Laminaria*[1] runs opposite to gradients of density of bryozoans and spirorbid tube worms settled on the fronds[2,3]. Bryozoan colonies attached to a *Laminaria* frond grow towards the younger region[4], where antibiotic production is lowest. It has been suggested that tannins produced by branch tips of *Sargassum* have an anti-fouling role[5], but we have seen no other clear evidence of such an effect, although many marine plants and animals remain remarkably free from encrustation by other organisms[6]. We have now found further evidence in several examples of differential settlement by spirorbid worms on algae and by a bryozoan on another species of bryozoan.

We had noticed that holdfast branches of *Laminaria digitata* (Huds.) Lamour on Pembrokeshire and Plymouth shores bear populations of *Spirorbis inornatus* L'Hardy and Quièvreux, always attached to the sheltered inner sides. The same spirorbid settles abundantly on *Himanthalia elongata* (L.) S. F. Gray, but only on the undersides of the button-like expansions which protect the attachment points of the alga. In laboratory experiments, which followed the usual procedures[7] and will be reported in detail elsewhere, we found that settling *Spirorbis* larvae invariably select those parts of the two algae, irrespective of the contours of the surfaces and of their orientation to light and gravity. We tested these two sites for differential production of antibiotics.

Disks 5 mm in diameter cut from the surfaces were tested by standard procedures[8] against *Staphylococcus aureus*, strain NCIB8244. This grew readily or formed indistinct clouded zones around surfaces normally shaded and colonised abundantly by epibionts (Fig. 1*a* and *c*), but left

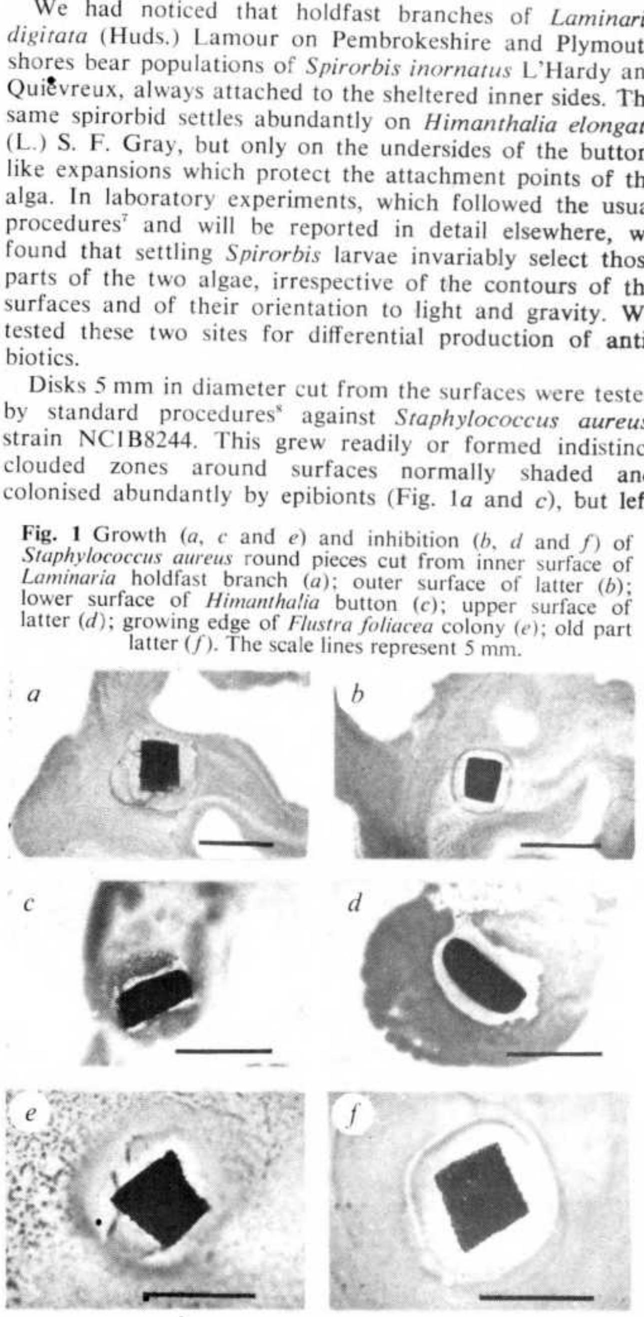

Fig. 1 Growth (*a*, *c* and *e*) and inhibition (*b*, *d* and *f*) of *Staphylococcus aureus* round pieces cut from inner surface of *Laminaria* holdfast branch (*a*); outer surface of latter (*b*); lower surface of *Himanthalia* button (*c*); upper surface of latter (*d*); growing edge of *Flustra foliacea* colony (*e*); old part latter (*f*). The scale lines represent 5 mm.

clearer and wider zones of inhibition around those normally exposed to light and unfavourable for the settlement of *Spirorbis* larvae (Fig. 1*b* and *d*).

We similarly tested the frondose bryozoan *Flustra foliacea* (L.), which is readily colonised by the bryozoan *Scrupocellaria reptans* (L.), with the initial settlement of larvae concentrated around the distal growing edge of the colony[4,9]. We found that region to be virtually devoid of antibacterial activity, whereas clear zones of inhibition usually appeared round pieces from older parts of the fronds (Fig. 1, compare *e* and *f*). The differences between pairs in each of the three experiments illustrated in Fig. 1 were all highly significant (Table 1).

Table 1 Mean widths of inhibition zones around 5-mm disks

Species	Region	No. of replicates	Mean width (mm) ± s.e.	*P*
Laminaria	Holdfast inner side	16	0.81 ± 0.13	< 0.01
Laminaria	Holdfast outer side	16	1.59 ± 0.15	
Himanthalia	Button lower side	24	0.28 ± 0.09	< 0.01
Himanthalia	Button upper side	24	1.00 ± 0.10	
Flustra	Growing edge	24	0.35 ± 0.11	< 0.01
Flustra	Old part of frond	24	1.35 ± 0.35	

Pieces cut from older parts of *Flustra* fronds, kept in a stoppered tube, emitted for several days a characteristic smell of lemons, whereas similar pieces from growing edges had a different smell and soon decomposed. This deserves further study, considering the insect-repellent reputation of citronellal, the apparent distaste for citronella grass shown by grazing buffalo[10] and the antiseptic properties of some monoterpene derivatives. The suggestion that tannins are the active agents in algae is supported by the finding that polyphenol production in *Laminaria* holdfasts seems to be increased at higher illuminations[11].

The settlement behaviour and growth orientation noted would confer advantages on the epibionts, ensuring a longer lifespan on *Laminaria* fronds, less competition for space on newly formed surfaces and greater protection from sand inside holdfasts or under *Himanthalia* buttons. Populations of *Spirorbis inornatus* are to some extent adapted to secure such advantages, for most larvae from parents on *Laminaria* settle on *Laminaria* rather than on *Himanthalia* (our unpublished results) whereas most from *Himanthalia* parents show the reverse preferences. But larval settlement on the insides rather than the outsides of *Laminaria* holdfasts, and on the lower rather than the upper sides of *Himanthalia* buttons, is not invariably the result of natural selection for avoidance of abrasion by sand, for similar behaviour is shown by larvae derived from a population of *Spirorbis spirorbis* L. at Swansea, which is confined to *Fucus* in pools 30 m from the nearest *Laminaria* (which is never colonised by *Spirorbis* in that locality) and 30 miles from the nearest *Himanthalia*. There could have been no recent evolutionary adaptation of that population to *Laminaria* or *Himanthalia*. The algae, on the other hand, presumably benefit from keeping their exposed surfaces clear for photosynthesis and there seems to be little need to discourage settlement on the sheltered surfaces inside holdfasts and under *Himanthalia* buttons. The antibiotics of *Flustra and Laminaria* seem to discourage only larvae, and are not obviously deleterious to older epibionts, which grow readily, no doubt protected by their greater size. The settlement on areas of new growth is not due to inability of growing regions to produce antibiotics, for several species of algae show maximum antimicrobial activity in regions which grow fastest[1,5]. In those species the growth regions are distal, suggesting that the antibiotics are involved in protection against epiphytes and macrograzers, as well as against the pathogenic invasions which would tend to follow damage by abrasion.

We thank Professor E. J. Denton and Dr D. C. Emerson for facilities, and Mrs Phyllis Knight-Jones, Professor J. S. Ryland and Professor P. J. Syrett for discussions.

Cell lineage analysis of germ cells of *Drosophila melanogaster*

THE initial events of differentiation of genetically identical nuclei within the eggs of higher organisms are generally believed to be triggered by a heterogeneous distribution of substances within the egg[1,2]. One of the clearest examples of such differential distribution of determinative substances concerns the posterior polar plasm of some insects. Morphological observations suggest that all cleavage nuclei in such insects have identical developmental potential, and that only the few nuclei that chance to migrate to the posterior polar region and thus to include a sufficient quantity of the morphologically distinguishable polar plasm, acquire the capacity to give rise to the germ line[3]. Various experimental approaches[4–8] have provided very strong, although not compelling [9] evidence for such a causal relationship between the polar plasm and germ line differentiation. Genetic fate mapping experiments described here strongly suggest that the germ cells of *Drosophila melanogaster* originate from the posterior-most region of the blastoderm, and they unequivocally rule out the possibility that the germ cells originate from a mid-dorsal position[10]. The posterior-most location of the germ cells supports, or at least is consistent with, the notion that the polar plasm determines whether or not a given cleavage nucleus will acquire the capacity to differentiate into a germ cell.

A priori, two possibilities can be distinguished. The first, as outlined above, states that "any nucleus may become a polar nucleus if it happens to move into the region of the posterior polar plasm, regardless of cell lineage" (ref. 3). The second assumes that the prospective germ cells are set aside during early cleavage before their interaction with the posterior polar plasm or with any other cytoplasmic region. One critical test between these two alternatives involves genetic determination of cell lineage relationships of the primordial germinal nuclei: only the first requires that they are mapped to the area of the blastoderm that contains the posterior polar plasm. The reason for this prediction is apparent, for example, from the observation that one ancestral nucleus in the posterior pole region can give rise to one daughter cell which contains the visible polar granules and one which does not[3], and hence that presumably only the former is likely to contribute to the germ line.

The technique of genetic fate mapping[11,12] provides one approach by which cell lineage relationships of various anatomical regions can be determined[8]. Using this technique, Falk *et al.*[10] located the gonads on the genetic fate map of *D. melanogaster* "about half way along the blastoderm near the mid-ventral line". They suggested therefore that "the assumption that the site at which a nucleus lands in the periplasm decides its fate has to be modified, at least for nuclei destined to give the gonads" (ref. 10).

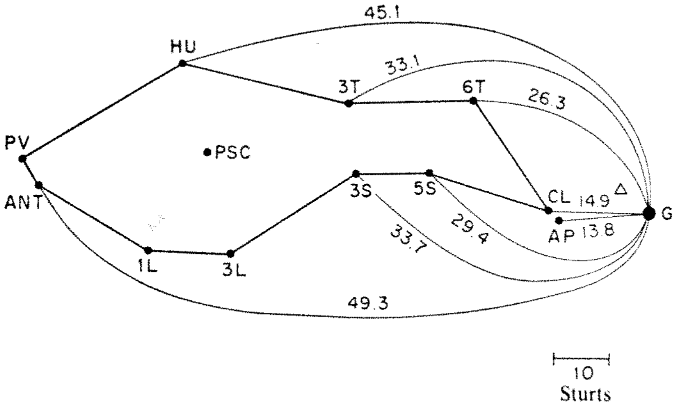

Fig. 1 Genetic fate map of the right half of *D. melanogaster* blastoderm, with special reference to the position of the germ cells. Because it was not possible to rule out a *priori* a bilateral symmetrical origin of the germ cells, data from germinally mosaic males were not included in the calculations of distances between the germ cells and various cuticular landmarks. But the general outline of the map, and, in particular, the posterior position of the germ cells, is preserved when the data from germinally mosaic males are also included or when the map distances are computed according to the suggested algebraic correction[19,22] for systems in which the mean proportion of mutant tissue is significantly different from 0.5. The open triangle represents the position of the germ cells triangulated on a map derived from 105 mosaic females and then superimposed on the map of 215 phenotypically mosaic males shown here. ANT, antenna; AP, anal plate; CL, clasper; GC, germ cells; HU, humeral bristles; PSC, posterior scutellar bristle; PV, post-vertical bristle; 1L, first leg; 3S, third hemisternite; 3T, third hemitergite.

Both the observations that some pole cells in *D. melanogaster* give rise to somatic cells rather than primordial germ cells[13], and the observation that in the wasp *Pimpla turionellae*, although characteristic pole cell formation and migration occur, germ cells are found in the absence of pole cells[14,15], seem to be compatible with this suggestion. But two other attempts[16,17] have been made to determine the developmental origin of the gonads by means of genetic fate mapping, and these gave a posterior position compatible with the hupothesis that the site at which a nucleus lands in the cytoplasm decides its fate. These inconsistent results are surprising in view of the reproducible interrelationships between cuticular landmarks that are reflected by many independently derived maps[11,12,16-23] and in view of the strong evidence for the validity of the fate mapping procedure[12,21,24].

All three investigations mapped whole gonads either at the larval stage[10,17] or at the adult stage[16]. It is well established that the gonads of *Drosophila* derive from two developmentally unrelated components: the germ cells which give rise to the germ line and mesodermal cells which give rise to the gonadal sheath and interstitial cells[8,25]. The nature of the interaction between these two components is unclear[13,25]. In addition, the attachment of testes in adult gynandromorphs to the developmentally distinct female oviducts causes degeneration of the testes[26]. These theoretical considerations, coupled with the technical difficulties encountered in fate mapping of internal organs and the need to use a functional, rather than morphological criterion for the germ nuclei, make it very difficult to resolve these contradictory results and their bearing on the hypothesis that the posterior polar plasm contains germ cell determinants. A clearcut resolution of this problem is therefore likely to emerge only from functional mapping of the germinal nuclei themselves, irrespective of other elements of the reproductive system[8]. The experiments described here constitute the first clearcut genetic evidence for the developmental origin of the germ cells, and they show that the germ cells of *Drosophila* do indeed originate from the general area that has been traditionally assigned to them by cytologists—the posterior tip of the egg.

Males of the constitution *y*–*y*$^+$ *Y*; *pal*–*pal* were crossed to XY, *y B* females[20,27]. The sons from this cross were screened for *pal*-induced somatic mosaicism for the extra Y chromosome; this can be detected by the appearance of yellow and non-yellow cuticular patches in the same male. The frequency of mosaicism among the F_1 males has not been calculated directly, but ranged approximately from 0.001 to 0.002. On average, each cuticular region was yellow in 40% of the mosaic males, non-yellow in 55% and mixed in the remaining 5%. The mosaic distribution of the entire cuticle of each rare mosaic male was recorded. Subsequently, each mosaic male was crossed to five to nine *yellow* females. These *yellow* females were kept in a stock in which all males carried the B^sY chromosome and thus any non-virgin yellow female could be detected from a phenotypic examination of her sons. The constitution of the germ cells of each 0–14-d old mosaic male was inferred from the phenotype of his sons: the germ cells of a male that only gave rise to non-yellow and fertile sons must have contained the extra marked Y chromosome; yellow and sterile sons indicate that they did not contain this extra Y chromosome, and when both phenotypes were found among the male progeny of a single male it could be assumed that such a phenotypically mosaic male was also germinally mosaic.

Out of a total of 260 phenotypically mosaic males obtained, six died shortly after their isolation and gave no offspring, 17 were sterile, six gave rise to less than 62 sons and 16 gave rise to some haplo-4 progeny. Of the remaining 215 mosaic males, 85 gave rise to *y* sons, 94 gave rise to *y*$^+$ sons and 36 to both *y* and *y*$^+$ sons. An average of 312 sons was observed per mosaic male and the smallest number of sons scored per male was 62. The data obtained from these 215 males made it possible to correlate the constitution of the germ cells to various cuticular landmarks and thus to determine their position on the genetic fate map of *D. melanogaster* (Fig. 1).

To rule out any sex-specific differences in the developmental origin of the germ cells and to obtain an independent corroboration of their posterior-most position (Fig. 1), an analogous investigation has been carried out with mosaic females. Males of the constitution *y*/*y*$^+$ *Y*; *pal*/*pal* were crossed to attached X *C(1)RM*, *y pn v*/0 females. The automatic virgin daughters obtained from this cross were screened for somatic mosaicism and their pattern of mosaicism was recorded. Subsequently, these mosaic females were crossed to *yellow* males. A total of 116 Y-chromosome mosaic females was obtained. The analysis, however, was based only on 105 mosaic females that gave rise to a minimum of 22 sons. The mean number of sons per female in this group was 98. Again, a fate map of cuticular landmarks was constructed and the location of the germ nuclei on this map was determined. Although there were some differences between this map and the map derived from mosaic males (Fig. 1), they were very similar in general outline and hence the map obtained from these 105 mosaic females is not reproduced here. Instead, the position of the germ cells in this map is superimposed on the map shown in Fig. 1.

Cell lineage in retinal development of mice studied in experimental chimaeras

IN vertebrate embryos, the optic cups develop as lateral outgrowths of the diencephalon, the rudiments of which are first recognised at the antero-lateral margins of the neural plate. Evidence accumulating from extensive studies with vital dyes[1–4], excision and transplantation experiments[5–7] in amphibian embryos have shown that the cell boundaries of the different areas of the central nervous system are already fixed at the early neurula stage when the presumptive retinal cells are located in the antero-median border of the neural plate. It has remained unresolved whether the two retinal primordia and the layers thereof are determined in a single or separate group of cells. It seems to us that the problem is one of cell lineage and can be analysed with genetic mosaics. The retinal pigment epithelium (RPE) is derived from the outer layer of the embryonic optic cup. In chimaeric mice, produced by aggregating morulae from albino and pigmented strains, the presence of two types of cells in the RPE has been reported[8–10]. Deol and Whitten[11] first noted that RPE of the two eyes of such chimaeras showed similar proportions of cells. It was recently observed that there is a close correlation in occurrence of chimaerism in the RPE and in the neural retina and between the two eyes of the individuals[12,17]. Here we present quantitative data on the relative proportion and spatial distribution of cells from the two donor genotypes in the RPE and compare them with the relative proportion of cells in the neighbouring melanocyte population of the choroidal layer of the eye. The results show that there is a marked similarity in the proportion of the cells of the RPE from the two eyes of the individual chimaeras suggesting a lineage relationship between the two retinal primordia.

Chimaeric mice were produced by aggregation of morulae from albino BALB/c and pigmented C3H strains[12]. The eyes were removed when the animals were 20–26 days old and 8 μm thick serial sections were prepared. Out of 67 individuals obtained, 43 had both albino and pigmented cells in their RPE. Of these only 2 animals showed unilateral chimaerism, whereas in the rest the RPE of both eyes were chimaeric. Eyes from 20 animals, including the two showing unilateral chimaerism and representing a broad spectrum of distribution, were used in this study. The RPE from every third section was first drawn with a camera lucida and the stretches of albino and pigmented cells were marked. Each drawing was scanned in an x–y plotter attached to a computer. The program was designed to straighten the curved profiles of the RPE, to measure the linear lengths and calculate the relative proportions of the two components, and to map the spatial distribution of the cells in a two-dimensional reconstruction by aligning the linear outputs of the successive sections. In contrast to the RPE which is a single layer of cells, the choroidal melanocytes are located in a thick multicellular layer. For quantitative assessment every tenth section was used and the relative proportion of the albino cells in alternate stretches of the sections in the microscopic field were scored as 100% or 0% if completely albino or uniformly pigmented, 50% when the two kinds of cells appeared equal in proportion, 75% or 25% when the albino cells appeared to be relatively more or less than the pigmented cells; the mean value from all the scorings in each eye, numbering 150–180, was taken.

When the relative proportions of the albino cells in the RPE of the left and the right eyes from each chimaera are listed in the decreasing order (Table 1) it is seen that the two individuals with unilateral chimaerism represent the two extremes with 99.6% and 0.4% albino cells respectively. Among the 18 individuals with chimaeric distribution in both eyes, the relative proportions of the albino cells vary from 99.6% to 5%; but show a high degree of correlation between the two eyes in each of these chimaeras. In the melanocyte population of the choroidal layer unilateral chimaerism is seen in 6 individuals. In 4 other animals chimaeric distribution is seen in the RPE but the choroidal melanocytes of both eyes are non-chimaeric. In animals showing chimaeric distribution in both layers the relative proportion of the cells in the choroid often differs considerably from the relative proportion in the RPE of the same eye. The difference in the relative proportion of the cells in the choroid layer of the two eyes of the individual chimaeras is also considerably more than that of the RPE.

The spatial pattern of cell distribution in the RPE of the two eyes from 10 out of 20 chimaeras analysed is shown in Fig. 1. Although examination of serial sections reveals that stretches of albino and pigmented cells may vary from a single cell to one of many cells, in the reconstructed map of the entire RPE, it is clearly seen that the two kinds of cell are not randomly scattered though considerable intermingling has occurred. Areas of varying sizes with predominantly one type of cell could be seen in all cases and often such areas appeared as radial sectors stretching from the optic nervehead to the periphery. The number and dimension of such sectors varied among the individuals but in a few cases 10 alternate sectors with predominantly albino and pigmented cells, as reported previously[10], could be recognised (Fig. 1. 48 left eye, 45 right eye).

A similarity between the RPE of the two eyes could conceivably result from random assortment if the two types of cells were uniformly mixed throughout the chimaeric embryo. Observations on chimaeric blastocysts of mice, in which cells of one component were labelled with H^3-thymidine (ref. 13) and in early post-implantation embryos of mouse ⟷ rat chimaeras, in which the cells could be

14	0.4	0	0	0

The relationship between the percentage of albino cells in the RPE of the left and the right eye can be expressed by the following linear regression equation: $y = 0.8 + x$ (y, right eye; x, left eye) and the coefficient of determination (r^2) is 0.97. The difference between the RPE of the two eyes did not reach statistical significance (t dependent; $t = 1.4003$ d.f. 19). The absolute difference in the relative proportion of albino cells between the choroidal layer of the left and the right eyes is greater than that of the RPE (t dependent; $t = 3.226$ d.f. 19 $P < 0.005$ one-tailed).

identified by immunofluorescence[14], suggest that the cells from the two donor components are not intimately mixed but remain in coherent clusters. Transplantation of presumptive retinal cells in early stage *Axolotl* embryo has been shown to result in growth of the cells derived from the graft within well defined radial sectors of the RPE[15]. Although more random distribution of the cells in the RPE of 12½-day-old chimaeric mouse embryos in comparison to that of the adult RPE has been reported[16], there is no indication that at 12.5 d or at earlier stages of development cell mixture was uniform throughout the RPE. Localised distribution of pigmented cells in the RPE of animals with more than 95% albino cells, as observed in this study, makes it unlikely that cell mixture could have been uniform enough to ensure equal division by random process.

The bilaterality of cell distribution in the RPE of chimaeric mice, more particularly in the individuals showing preponderance of one of the cell types, suggests an orderly mechanism of cell deployment. It is concluded that the cells giving rise to the two optic cups are derived from

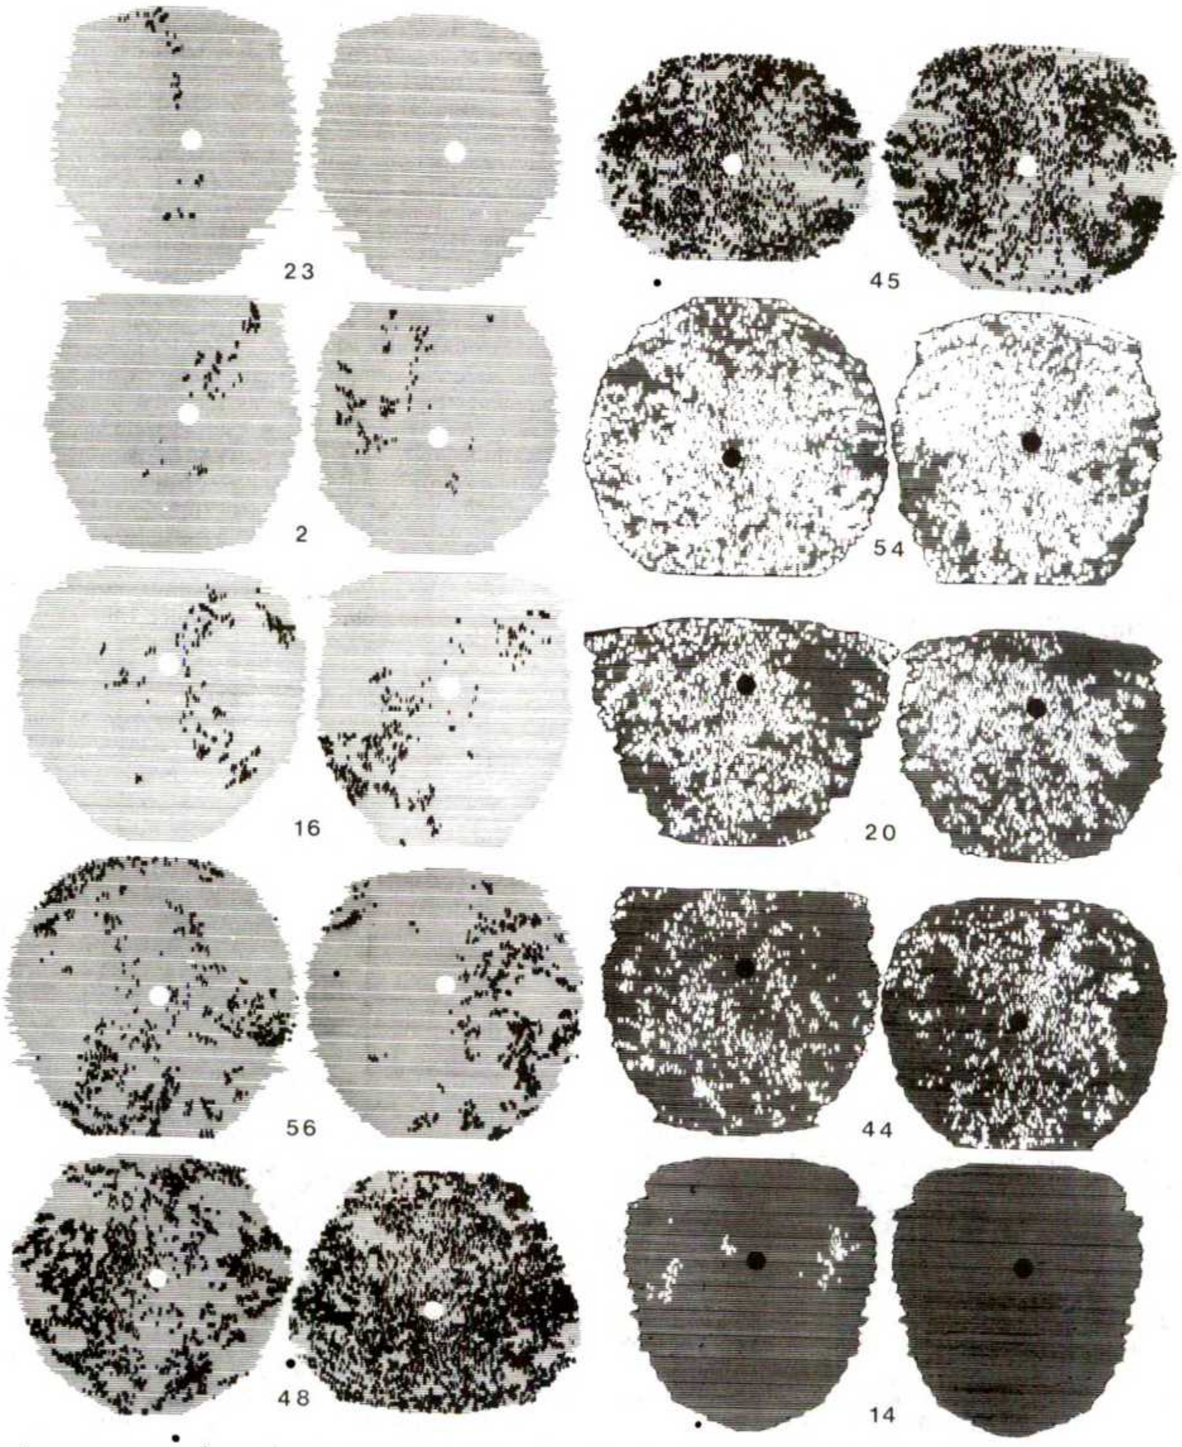

Fig. 1 Spatial distribution of albino (white) and pigmented (black) cells in the retinal pigment epithelium of the left and the right eyes from a series of chimaeric mice. The numbers indicate individuals listed in Table 1. The circle near the middle of each figure represent the optic nerve head.

common precursor cells, the lineage of which is so programmed that the daughter cells are segregated into two discrete lateral groups. It seems likely that such a mechanism may operate in the development of bilaterality of the central nervous system as a whole.

Inductive capacity of irradiated dermal papillae

MAMMALIAN hair follicles are specialised skin appendages which produce a series of hairs, one after another, in a regular cyclical fashion. The hair itself is composed of dead epithelial cells containing large amounts of keratin. During growth of the hair the epithelial cells at the bottom of the follicle surround the dermal papilla and divide rapidly. The dermal papilla is derived from mesenchyme and is composed of non-dividing cells. The importance of the dermal papilla in maintenance and control of hair cycles has been assumed for many years but little direct evidence of its function has been demonstrated. Geary[1] caused permanent removal of rat body hair by applying 1,720 rad of X irradiation. He believed that he had caused destruction of the dermal papilla which in turn resulted in permanent epilation. We report here a study on the effect of heavy doses of irradiation on the dermal papilla and epithelial elements of the hair follicle. We have found that high doses of irradiation, which cause permanent epilation, destroy the epithelium but leave the dermal papilla anatomically and functionally intact so that even on transplantation it can induce a series of new hairs.

The mystacial vibrissal follicles of rats and mice form a remarkably constant pattern. Each follicle regularly produces a series of vibrissae with constant characteristics. Their lengths can be easily measured in the live animal by the capillary tube method[2,3]. The four largest vibrissal follicles, designated by Danforth[4] as E, F, G and H, form a vertical column in the most posterior position and the 'a' column of five slightly smaller vibrissal follicles are found immediately anterior.

A single dose of X ray was applied locally to the vibrissal follicles in young mice. Permanent epilation in the E, F, G and H column of follicles took place after a dose of 2,500 rad (ref. 5). Five months later these follicles were examined histologically and were found to have an isolated dermal papilla at the bottom of the follicle. This dermal papilla was rounded in shape and packed with cells. No epidermal cells were seen (Fig. 1). Permanent epilation was therefore considered to be a result of complete destruction of the epidermal constituents of the follicle while leaving the dermal papilla histologically intact.

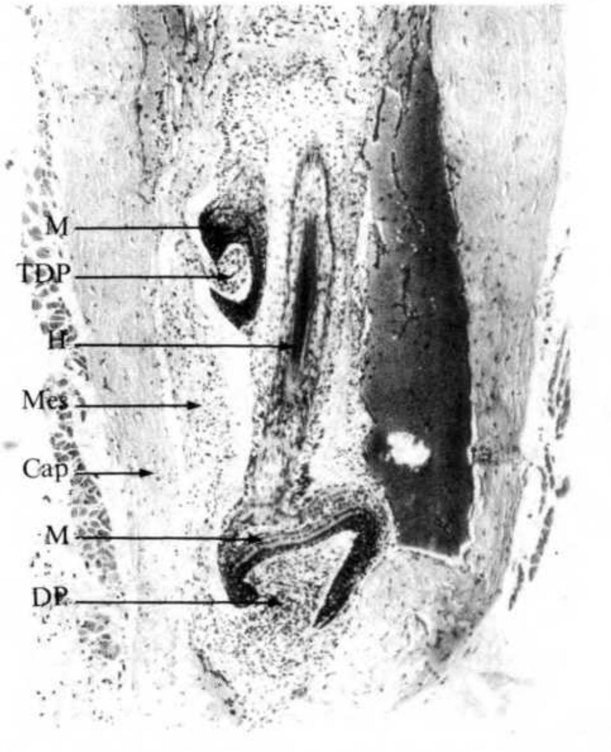

Fig. 1 A longitudinal section through a C_3H mouse (female) follicle given 2,500 rad of X irradiation. There is no trace of the matrix or other epithelial elements in the hair canal. (× 100.) DP, dermal papilla; BS, blood sinus; Cap, capsule.

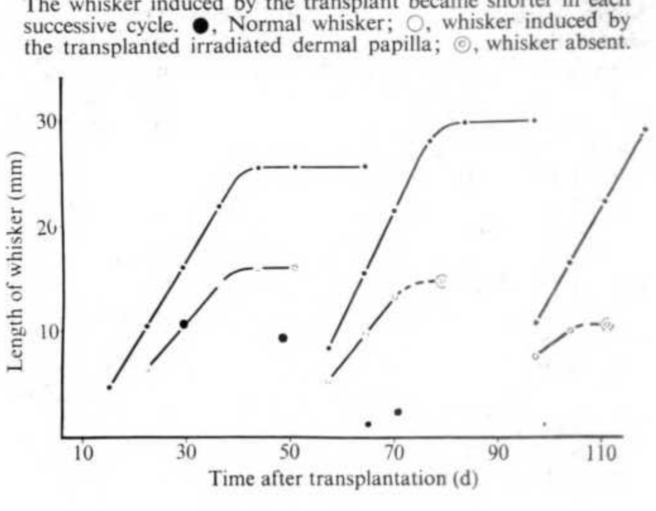
To determine whether the dermal papilla in a heavily irradiated follicle is physiologically functional, it would be necessary to bring the irradiated dermal papilla into contact with normal follicular epithelium. To achieve this E, F, G and H vibrissal follicles in Wistar-derived rats were irradiated with 5,000 rad of X irradiation and on the next

Fig. 2 Growth curves of the two rat whiskers observed growing from Ia follicle after transplanting a heavily irradiated dermal papilla into its hair canal. The normal was a few mm shorter in the first cycle probably because of damage during transplantation. The whisker induced by the transplant became shorter in each successive cycle. ●, Normal whisker; ○, whisker induced by the transplanted irradiated dermal papilla; ◎, whisker absent.



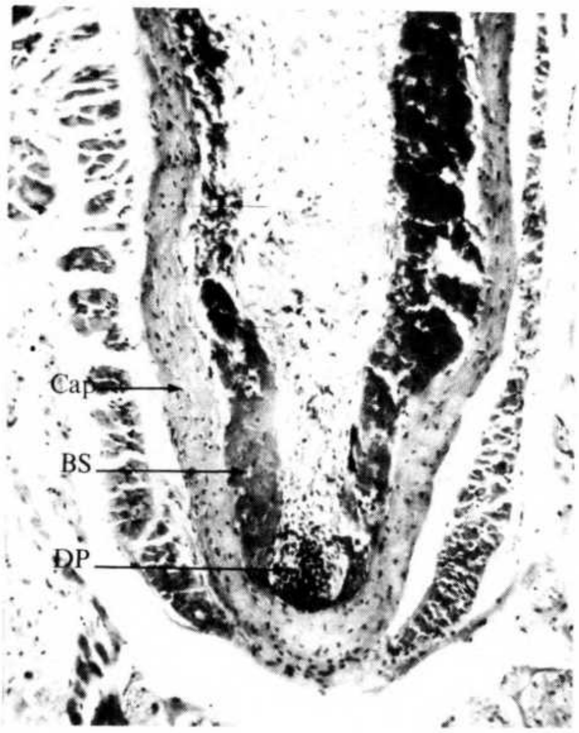


Fig. 3 The bottom end of an F follicle which received two dermal papillae irradiated with 5,000 rad. The vibrissae are inside the hair canal. The superior transplanted dermal papilla has made connection with the mesenchymal blood plexus. The second transplanted dermal papilla has distorted the normal at the bottom of the follicle and is not clearly shown in this section. (× 95.) Abbreviations as in Fig. 1; also M, matrix; Mes, mesenchymal sheath; H, hair induced by the host dermal papilla; TDP, highly irradiated, transplanted dermal papilla.

day the animals were killed and their dermal papillae were excised and transplanted into normal vibrissal follicles in normal rats. Three to four weeks later an extra whisker was observed growing alongside the normal vibrissa of the host follicle in approximately one third of the follicles. The whiskers induced by the irradiated dermal papillae were observed for two to three hair cycles before the rat either died or was killed. The induced vibrissae were shorter than the normal in length and had a slower rate of growth (Fig. 2).

Histologically, the induced hair bulb looked normal in most respects except for its situation (Fig. 3). We concluded that new hairs were induced by the transplanted dermal papillae wherever they were placed inside the hair follicle even if it was in the blood sinus. The length and size of the induced hair was dependent on the size of the transplanted dermal papilla. The whiskers produced by the irradiated and transplanted dermal papillae became shorter in successive cycles. They were more than 30% shorter at the end of three successive cycles.

Thus if heavily irradiated, permanently epilated follicles are left *in situ* the epithelium is destroyed but the dermal papilla remains as a recognisable but rounded mass of apparently viable cells. Transplantation of heavily irradiated dermal papillae into normal vibrissal follicles, however, induced additional new hairs which were observed for up to three successive cycles.

These findings show that a massive dose of X irradiation eliminates the epithelial elements of the growing hair, but does not abolish the inductive capacity of the dermal papilla. The failure of these dermal cells to display damage during at least 5 months observation following irradiation probably occurs because they do not divide; an analogous situation is found in the resistance to radiation of adult mammalian neurones[6].

Vesicular disruption of myelin simulated by exposure of nerve to calcium ionophore

EXPERIMENTAL allergic encephalomyelitis (EAE) and experimental allergic neuritis (EAN) are autoimmune demyelinating conditions brought about by sensitisation to central and peripheral myelin extracts, respectively. The lesions are the result of a delayed hypersensitivity-type reaction which can be passively transferred by lymphoid cells but not by sera[1–4]. Demyelination occurs in areas of cellular infiltrate. This process is mediated in part by mononuclear cells which invade and phagocytise the target myelin tissue. A vesicular transformation of myelin sheaths is known to occur in close proximity to these invading mononuclear cells[5–7]. The nature of the myelin vesiculation is unclear; however, these changes have been emphasised as a characteristic accompaniment of autoimmune demyelination in experimental animals and in human peripheral nerve disease[8]. The present study reports the occurrence of the same type of myelin alteration in excised rat peripheral nerve fibres when incubated under conditions which promote a selective influx of calcium ions into the tissues.

Multiple 15-mm segments from the same excised and desheathed rat sciatic nerves were simultaneously incubated in oxygenated Ringer's solutions with and without the addition of A23187, 10 mg l^{-1}, and in calcium-free Ringer's solution containing ionophore and EGTA, 1 mmol l^{-1}, to chelate endogenous calcium. After 30-, 60- and 120-min incubations at 37 °C, the tissues were fixed by immersion and processed for electron microscopic examination as already described[9].

A vesicular disruption of myelin appeared as a distinctive alteration of nerve fibres incubated in the presence of both calcium and A23187. These changes were characterised by progressive vesicular transformation of myelin occurring along the surfaces of myelin sheaths, leading to increasing accumulations of a vesicular or foamy membranous meshwork adjacent to the remnants of original myelin sheaths. After 30 min, early vesicular changes could be seen as multiple vesicular eruptions along the inner and outer surfaces of compact myelin sheaths (Fig. 1). Progression of vesicular alterations was evidenced after 60 and 120 min by massive accumulations of a foamy material in myelinated fibres (Fig. 2). Vesicular alterations occurred predominantly in nerve fibres situated around the periphery of the nerve fascicles immediately beneath a thin residual perineurial investment (Fig. 3). The location of these fibres rendered them most susceptible to the effects of the incubation media as well as the fixative solutions. The penetration of lipophilic ionophore may also have been limited by the high lipid content of the nerve tissue.

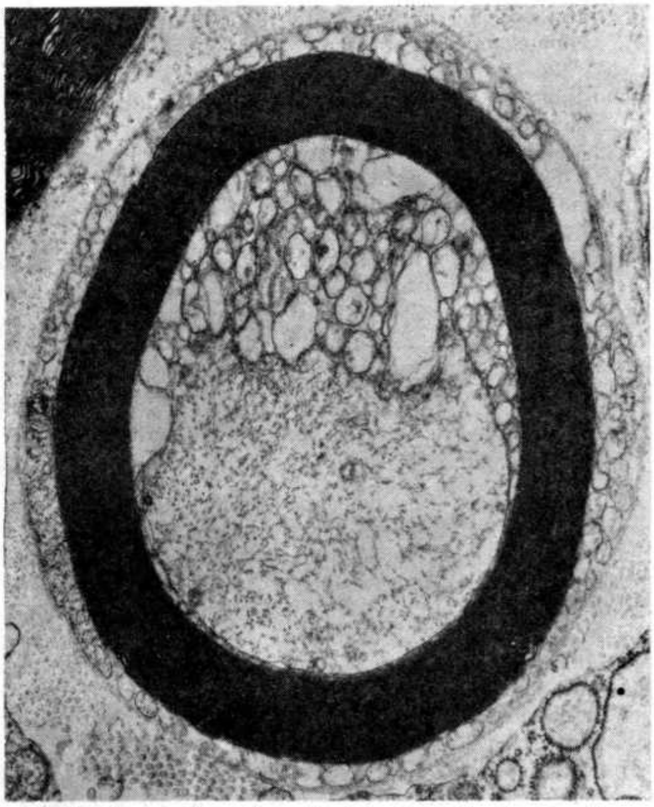

Fig. 1 Cross section of myelinated rat peripheral nerve fibre showing early vesicular disruption of myelin after 30-min exposure to A23187 (10 μg l^{-1}) in Ringer's solution containing $CaCl_2$ (4 mmol l^{-1}). Arrays of vesicular profiles occur along the inner and outer surfaces of the otherwise intact lamellar myelin sheath. (×14,000.)

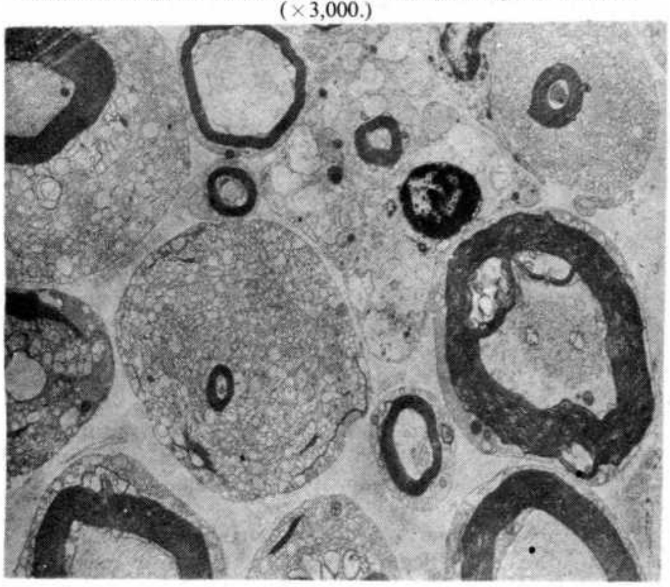
A vesicular disruption of myelin was not seen in control nerve segments incubated in the absence of either ionophore or calcium. The vesicular type of myelin alteration was readily differentiated from preparative myelin artefacts which were scattered through the nerve fascicles and occurred with limited but equal frequency in experimental and control tissues. These myelin artefacts were characterised by concentric loosenings of myelin lamellae or by focal distortions or extrusions in the laminated cylindrical form of the myelin sheath.

Fig. 2 Cross section of nerve fascicle showing several fibres with more advanced states of myelin vesiculation following 120-min incubation in Ringer's solution containing A23187. A vesicular or foamy network has accumulated in Schwann cell cytoplasm adjacent to the residua of compact myelin sheaths. (×3,000.)



Incubations were conducted between *p*H 7.2 and 7.4, and visually monitored by inclusion of phenol red (1 : 10,000) in the media. Under these conditions, A23187 has selective high affinities for calcium and magnesium[10,11]. Both experimental and control incubations contained $MgCl_2$ (1 mmol l^{-1}), but only the experimental incubation contained both ionophore and calcium, a condition associated with the influx of calcium into tissues. The ability of A23187 to translocate calcium across cell membranes is well known and is believed to be due to a physical envelopment of calcium by ionophore, thereby rendering calcium lipid soluble and membrane permeable[12]. The direction of ionophore-mediated transmembranous movement of calcium is down the calcium concentration gradient. In calcium-free media containing EGTA, the calcium gradient is reversed. Incubation of nerve under these conditions acused separation of axolemmae from internal Schwann cell membrances of myelinated fibres, morphological features indicative of reduced tissue calcium observed following calcium deprivational conditions in tissue cultured peripheral nerve[13]. The absence of myelin vesiculation under these conditions suggests the existance of a subthreshold calcium level, insufficient to induce myelin vesiculation.

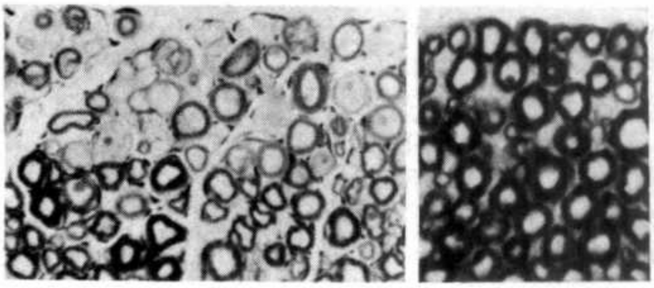


Fig. 3 Comparison of myelinated fibres along lateral edge of experimental (left) and control (right) nerve segments incubated for 120 min in Ringer's solutions with and without A23187. Superficial myelinated fibres in the experimental nerve segment reveal dissolution of compact myelin manifested by a loss in density of circular profiles, which represent cross sections of compact myelin sheaths. Additional control incubations in media containing ionophore but lacking calcium showed uniform preservation of compact myelin sheaths. Thin section of epoxy-embedded tissue stained with toluidine blue. (×450.)

These results imply the existence of calcium-reactive sites within the myelin sheath which induce myelin vesiculation upon their exposure to calcium. These calcium-reactive sites seem to be located within the myelin lamellae in such a manner as to render them inaccessible to calcium in the extracellular spaces in physiological conditions or to calcium present in the intraperiod space during incubations in hypotonic Ringer's solution[14]. Their relationship to calcium-binding sites of myelin[15] is unknown. Calcium-binding sites of plasma membranes may be exposed by detergent pretreatment[16]. The vesiculation of myelin which occurs in nerves exposed to lysophosphatidyl choline[17] could exemplify a detergent-induced exposure of calcium-reactive sites in the myelin sheath.

Myelin vesiculation which occurs in pathological conditions may also represent the manifestations of calcium interaction with components of the myelin sheath. Exposure of calcium-reactive sites could well occur during the degradation of myelin sheaths, resulting in occasional focal vesicular alterations reported or depicted in these circumstances[18–22]. The myelin vesiculation of cell-mediated immunological demyelination, however, is distinguished by its prominence and occurrence along the surfaces of intact myelin lamellae in the vicinity of infiltrating mononuclear cells[7-9]. The distribution of change in close proximity to these cells is strongly indicative of their complicity in the causation of myelin vesiculation. Numerous humoral factors have been identified as mediators of cellular immunological reactions[23] although the mechanisms underlying their activities have often remained obscure. A humoral mediator of myelin vesiculation would have particular interest in that its mechanism of action may well be operative by promoting calcium penetration into myelin membranes. A calcium influx is well recognised as a trigger for many biological phenomena. Accordingly, a humoral factor with the ability to increase calcium permeability of membranes could serve as a powerful means of effecting immunological reactions.

This investigation was supported by grants from the US NIH. A23187 was a gift from Dr R. L. Hamill.

Cancer-induced cytolysis of normal bone marrow cells

MOST investigations of the invasive process of cancer have involved microscopic studies of tumour spread after injection of cancer cells into experimental animals[1–4]. Attempts to investigate tumour invasiveness using organ or parabiotic cultures have met with limited success[5–7] We have evaluated tumour-mediated cytolysis of normal rat marrow cells using suspension cultures containing Walker-256 carcinosarcoma cells and ^{59}Fe-labelled rat bone marrow cells. This mixed cell culture system seems to provide a promising approach to the further understanding of cancer invasiveness.

Interactions between cancer cells and normal cells were evaluated by a modified cytotoxicity assay[8] Walker-256 carcinosarcoma cells (from Arthur D. Little Co. under the auspices of the NIH) were isolated from the ascites tumour which accumulated 7 d after intraperitoneal transplantation of 1 × 10^6 Walker-256 cells to adult Wistar rats. Tumour cells were separated from erythrocytes by centrifugation (400*g*) on a sterile gradient of a sucrose polymer and diatrizoate salts (LSM Solution, SG, 1.077–1.080, Litton). Tumour cells, located at the interface, were collected, washed twice and suspended in nutrient medium. More than 98% of the isolated cells were identified morphologically as tumour cells.

Rat marrow target cells were collected and prepared for suspension culture as before[9] Bone marrow cells (1 × 10^7 per ml) were labelled with 2 μCi ^{59}Fe per ml (ferrous citrate, Mallinckrodt) for 4 h at 37 °C. (After a 4-h incubation of rat marrow cells with ^{59}Fe-transferrin, Storring and Fatih reported that cytoplasmic ^{59}Fe accounted for approximately 78% and stromal ^{59}Fe for 22% of all ^{59}Fe incorporated[10]. Cytoplasmic ^{59}Fe consisted of haemoglobin iron (65%), ferritin iron 20% and an unidentified low molecular weight iron (15%)) The cells were washed four times to eliminate unincorporated label, suspended in nutrient medium (70% NCTC-135, 30% heat-inactivated foetal calf serum, Grand Island Biological, with penicillin and streptomycin) and added to various concentrations of Walker-256 cancer cells. The cell suspensions were mixed thoroughly by inversion and incubated in 10 × 75-mm friction cap tubes (Falcon) in 5% CO_2 and 95% air for 18 h at 37 °C. The mixed cell suspensions were then centrifuged at 400*g* for 10 min (4 °C), and the radioactivity in the supernatant and cell pellet was measured. Cytotoxicity is expressed as a function of the release index (RI)

$$\mathrm{RI} = \frac{\text{radioactivity released due to cell death (supernate)} \times 100}{\text{total radioactivity (supernatant and cell pellet)}}$$

Because most of the ^{59}Fe is taken up by haemoglobin-producing nucleated marrow cells (erythroblasts)[11], this technique measures principally the release of haemoglobin and non-haemoglobin iron-containing molecules from erythroblasts, and has been termed erythroblast cytotoxicity assay[12]. As in lymphocyte cytotoxicity studies[13], the baseline RI of marrow cells varied between experiments, making control cultures essential (^{59}Fe-labelled marrow cells alone) with each experiment. Significant differences between triplicate cultures of marrow cells alone and marrow cells cultured with Walker-256 cells were determined by Student's *t* test[14].

The ability of Walker-256 cancer cells to initiate marrow cell cytotoxicity is typified by the data in Table 1. Similar results were obtained in nine other experiments The spontaneous RI for marrow erythroblasts cultured alone was 18.5 ± 1.3% (s.e.m.) The increasing cytolysis of marrow cells cultured with Walker-256 cells was proportional to the ratio of tumour cells to marrow cells. In cultures containing equal numbers (1 × 10^7 cells) of Walker-256 and marrow cells the RI was 49.3 ± 1.2%. Marrow cell viability, as determined by Trypan blue exclusion, was inversely proportional to the number of tumour cells in culture. ^{51}Cr-labelling of rat marrow cells also resulted in significant, but less tumour-mediated marrow cytolysis

Table 1 Marrow cytotoxicity Trypan blue exclusion (viability) and RI

Ratio tumour cells to marrow target cells	RI (% ± s.e.m.)	Marrow viability (%)
0:1	18.5 ± 1.3	90
0.13:1	27.5 ± 1.0*	73
0.25:1	32.4 ± 1.0*	77
1:1	49.3 ± 1.2*	59
10:1	60.6 ± 1.4*	—
1 (alcohol-treated):1	17.9 ± 0.8	88
Tumour cell sap.:1 (from 1 × 10^8 cells)	18.3 ± 0.7	87
Ascitic fluid supernate:1	18.1 ± 0.8	76
1 Mouse spleen:1	21.0 ± 0.4	87
1 Rat spleen:1	18.9 ± 0.6	89

RI, release of ^{59}Fe from labelled rat bone marrow cells incubated for 18 h with viable Walker-256 carcinosarcoma cells, alcohol-treated Walker-256 cells, cell-free tumour ascitic fluid, or normal spleen cells

*$P < 0.01$, significantly different from control cultures containing ^{59}Fe-labelled rat marrow cells alone (0 tumour cells to 1 marrow cell)

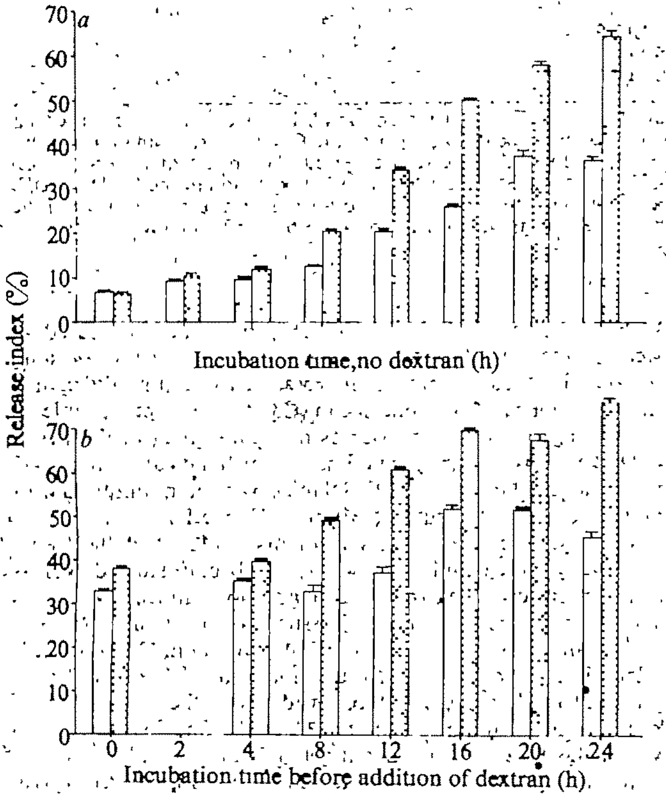
Tumour-mediated cytotoxicity of erythroblasts required intact tumour cells. No cytolysis was noted with alcohol-treated Walker-256 cells or the supernatant from the tumour ascitic fluid (Table 1) The cell sap of sonicated Walker-256 cells (100,000*g* for 90 min) also had no effect on erythroblast cytolysis When the effect of temperature on marrow RI was evaluated, no tumour-induced marrow cytolysis was observed in 24-h cell cultures maintained at 4 °C and was minimal at 25 °C. Maximum marrow cytolysis was observed at 37 °C.

To evaluate the ability of non-malignant cells to mediate marrow cytotoxicity, ^{59}Fe-labelled normal rat marrow cells were cultured with an equal number of normal mouse or rat spleen cells. Spleen cells did not significantly increase rat marrow erythroblast cytolysis (Table 1).

The progression of tumour-induced marrow cytolysis was evaluated by incubating tumour and marrow cells together and measuring RI at 0, 2, 4, 8, 12, 16, 20 and 24 h. As Fig. 1*a* shows, no significant increase in the release of ^{59}Fe from marrow cells was evident before 4 h, but marrow cytolysis increased during the next 12 h.

The requirement for intercellular contact between tumour cells and marrow cells during cytolysis was evaluated by a modification of Martz's method[8]. Equal numbers of Walker-256 cancer cells and ^{59}Fe-labelled marrow cells were incubated for 24 h in suspension cultures as described above. At specified intervals, however, 3 volumes of 10% high molecular weight Dextran (average 500,000. T-500, Pharmacia) in complete culture medium was added to each culture and mixed. Incubation was then completed and RI was measured. As Fig. 1 shows, erythroblast cytolysis increased as the duration of cell contact (before addition of Dextran) increased. When cell interaction was minimised by addition of high molecular weight Dextran at the initiation of culture (0 h), tumour-mediated marrow cytolysis was minimal.

Fig. 1. Cytolysis of ^{59}Fe-labelled marrow cells cultured alone (senescent lysis, clear bars) or with an equal number of tumour cells (senescent lysis and tumour-mediated lysis, shaded bars). *a*, Temporal progression of marrow cytolysis. Suspension cultures of marrow cells or marrow and tumour cells in nutrient medium were initiated at $t=0$ and terminated after 0, 2, 4, 8, 12, 16, 20 or 24 h of incubation. The cultures were centrifuged and the RI (mean ± s.e.m.) of triplicate cultures was calculated. *b*, Requirement for continuous marrow-tumour cell interation in order to obtain maximal tumour-mediated marrow cytolysis. Suspension cultures of marrow cells or marrow and tumour cells were initiated at $t=0$ and after 0, 4, 8, 12 16, 20, or 24 h of culture, 3 volumes of 10% Dextran in complete medium were added with vigorous mixing. Cultures were reincubated at 37 °C to give a total of 24 h of incubation. Cultures were then terminated and the RI of triplicate cultures was calculated. Minimal tumour-mediated marrow cytolysis was observed when Dextran was added within 4 h of the initiation of culture



Walker-256 cancer-mediated cytolysis of ^{59}Fe-labelled rat erythrocytes (labelled *in vivo* by intravenous injection of ^{59}Fe into rats 3 d before use of erythrocytes) was also demonstrated. The spontaneous release (RI) of ^{59}Fe from rat erythrocytes cultured alone was 1.5% in 20 h. The RI of rat erythrocytes cultured with Walker-256 cells (1:1 ratio) was 37.7%.

To determine whether the cytolytic interaction of Walker-256 tumour cells and erythrocytes was independent of phagocytosis, the phagocytic ability of Walker-256 tumour cells was evaluated by the method of Walker and Demus[15]. Tumour cells, collected and prepared as described above, were incubated for various times with erythrocytes labelled *in vitro* with ^{51}Cr. At the end of incubation the cells were centrifuged and the radioactivity in the supernatant (S_1) was determined. The cell pellet containing tumour cells, phagocytised ^{51}Cr-labelled erythrocytes and intact ^{51}Cr-labelled erythrocytes was suspended in distilled water and left at room temperature for 15 min. By this technique the engulfed erythrocytes would be protected from hypotonic lysis and ^{51}Cr would remain with the pellet. The cells were then centrifuged and the radioactivity in the supernant (S_2) and the pellet (P) was determined.

The phagocytosis index (%)

$$= \frac{\text{c.p.m. in pellet (P) after water lysis}}{\text{total c.p.m. } (S_1+S_2+P)} \times 100$$

was calculated. The phagocytosis of labelled erythrocytes by tumour cells was compared with the value obtained when ^{51}Cr-labelled erythrocytes, cultured without tumour, were subjected to hypotonic lysis, and the pellet-associated radioactivity was determined as described above. The phagocytosis index for erythrocytes cultured alone was 10.9±2.2% and for erythrocytes cultured with tumour was 12.6±0.5%. These values are not significantly different from each other ($P > 0.1$). Thus, in contrast to the murine reticulum cell sarcoma described by Ralph and Nakoing[16], Walker-256 breast carcinosarcoma is cytolytic both to nucleated and non-nucleated erythroid cells, but has no phagocytic capability in the system described above. Marrow–tumour cell cultures were also examined by electron microscopy, revealing no evidence of tumour phagocytosis of marrow cells.

Our findings indicate that Walker-256 carcinoma cells mediate the cytolysis of rat erythroblasts and erythrocytes in suspension cultures by a cell–cell interaction which is temperature-dependent and independent of phagocytosis. This cytolytic effect requires intact, viable Walker-256 cancer cells and, in contrast to lymphocyte-mediated cytotoxicity, will occur with a low effector cell-to-target cell ratio

H–2^{a}- associated alloantigen expressed by several transplacentally-induced lung tumours of C3Hf mice

CELL surface changes accompanying malignancy may result in the expression by the tumour cells of antigens recognisable by the host's immune system. It is interesting to know whether nascent tumours express common tumour-associated antigens and what, if any, is the relationship of these antigens to histocompatibility alloantigens. We have addressed these questions by testing a series of early passage, transplacentally induced murine lung tumours for a cross-reactive histocompatibility locus-coded alloantigen. A common transplantation alloantigen was readily detected on six of 15 lung tumours tested.

According to the concept of immune surveillance, a major function of the immune system is the detection and elimination of nascent autochthonous tumours[1-3]. The cytotoxic T-cell-mediated immune response evoked in mice against allogeneic cells is directed primarily against cell surface components coded for by the K and D regions of the H–2 major histocompatibility complex (MHC) (ref. 4). The specificity of T-cell-mediated immunity against chemically modified[5,6] or virally infected[7-11] syngeneic cells is also determined by these MHC-coded components. Cytotoxicity mediated by T lymphocytes against certain long term transplanted murine leukaemias can be inhibited by antisera directed against the H–2 antigens expressed by the leukaemia cells[12,13]. We have demonstrated that the tumour-associated transplantation antigen on a transplacentally induced lung tumour of a C3Hf/HeN mouse is similar or identical to an antigen coded for by the K region of the MHC of strain A mice. Thus radioresistant syngeneic immunity can be induced against this tumour, designated 85, by immunising C3Hf mice with normal tissues of strains A, B10.A and B10.A (2R), but not C3Hf, B10 or B10.A (5R) mice[14]. These studies suggest that derepressed or altered components coded for by the MHC may provide the mechanism of recognition of nascent tumours by the cellular immune system. The MHC is subject to mutation[15] and antigenic deviation between the MHC-coded antigens expressed by a long term transplanted tumour and by the normal tissues of the mouse strain of tumour origin might occur during repeated passage of the tumour. Studies of the specificity of the MHC-coded antigens expressed by long term transplanted tumours cannot, therefore, be unequivocally extrapolated to the MHC-coded antigens expressed by nascent tumours. Therefore, we have studied 14 additional transplacentally induced lung tumours of C3Hf mice after either the 1st or 2nd *in vivo* passage for the expression of the strain-A-associated alloantigen detected on the 85 lung tumour

Lung tumours were induced by a single transplacental administration of 1-ethyl-1-nitrosourea (ENU) to pregnant C3Hf mice (0.5 µmol per g body weight). The mice were injected between days 13 and 16 of gestation. Progeny mice were killed at approximately 1 yr of age and lung tumours greater than 5 mm in diameter were transplanted as fragments into syngeneic C3Hf mice. Fourteen tumours grew on 1st passage. Some of the tumours were retransplanted into a second group of syngeneic recipients. Tumour tissue from either the 1st or 2nd *in vivo* passage was collected and cut into approximately 1-mm square fragments. These fragments were stored in a 10% dimethyl sulphoxide solution under liquid nitrogen. Groups of C3Hf and (C3Hf × A)F$_1$ hybrid mice were inoculated intradermally with a single fragment of tumour as described previously[15,16]. Tumours which grew were excised from the tumour-inoculated mice. Control C3Hf mice were inoculated with a lung tissue fragment from either strain B10.A (H–2^{a}) or B-10 (H–2^{b}) mice. Immunised mice were X-irradiated (400 R) and challenged with 10^{6} 85 tumour cells. Tumour growth was measured at weekly intervals. Preimmunisation with five of the 14 lung tumours induced radioresistant cross-reactive immunity against the 85 tumour in C3Hf but not in (C3Hf × A)F$_1$ mice (Table 1). The linkage of the 85 tumour associated antigen to the MHC of H–2^{a} mice is shown by experiments which indicate that anti-85 immunity can be induced in C3Hf mice by preimmunisation with lung tissue of B10.A but not B10 mice (Table 1).

The results indicate that six out of 15 (40%) of the transplacentally induced lung tumours of C3Hf mice studied express a common cross-reacting transplantation antigen which is similar or identical to a normal tissue alloantigen of H–2^{a} mice. The finding of this common transplantation, MHC-coded, alloantigen is consistent with the important role attributed to modified or derepressed MHC products in the recognition of nascent autochthonous tumours[3,12,13,16,17]. The frequency with which the H–2^{a}-associated antigen is expressed also suggests that a clearly definable alteration in genetic regulation or syn-

Table 1 Ability of six transplacentally-induced lung tumours of C3Hf mice to induce radioresistant immunity in C3Hf, but not in (C3Hf × A)F$_1$ mice, against the 85 tumour

Pre-immunisation	Tumour growth in X-irradiated mice			
	C3Hf mice		(C3Hf × A)F$_1$ mice	
	Tumour incidence	Mean tumour diameter ± s.e. (mm)	Tumour incidence	Mean tumour diameter ± s.e. (mm)
Nil	10/10	10.8 ± 1.1	8/8	15.1 ± 1.0
85	1/9	0.3 ± 0.3*	8/8	12.0 ± 1.6
38	1/10	0.4 ± 0.3*	8/8	12.3 ± 1.4

320 M-1	2/9	3.3 ± 1.3*	10/10	15.0 ± 0.8
321 M-3	7/10	4.9 ± 1.1*	9/9	14.0 ± 0.6
Other tumours (9 total)	88/89	10.3 10.8 11.3 12.3 12.6 12.7 13.2 14.1 15.7	NT	NT
B10 lung	8/8	12.5 ± 0.8	NT	NT
B10.A lung	0/8	0.0 ± 0.0	NT	NT

Palpable tumours were present at 1 week after tumour inoculation in all (C3Hf × A)F$_1$ recipients and in all but one C3Hf recipient which received tissue from the nine non-cross-reacting lung tumours As indicated by tumour incidence, most of the C3Hf mice pre-immunised with tissue from the six cross-reacting lung tumours failed to develop tumours during a 2-month observation period. The mean diameters (±s.e) recorded here were those obtained 4 weeks after tumour inoculation in the C3Hf mice and 3 weeks after tumour inoculation in the (C3Hf × A)F$_1$ mice. Results marked with an asterisk indicate a significant difference from tumour growth in that group compared with tumour growth in the group not pre-immunised ($P < 0.001$). The other values were not significantly different from the control group ($P > 0.5$). NT, not tested.

thesis of the MHC-coded components is associated with lung tumour development in C3Hf mice.

Antibody-enhanced dengue virus infection in primate leukocytes

DENGUE viruses, types 1–4, are arthropod-borne flaviviruses which cause dengue shock syndrome (DSS) in humans possessing pre-infection antibody, passively acquired or derived from heterotypic infection[1]. Although the immunopathological mechanism of DSS is not fully understood, experimental studies suggest that dengue virus-production is immunologically regulated. Monkeys with monotypic immunity to dengue types 1, 3 or 4 viruses, when challenged with dengue 2, had significantly higher levels of circulating virus than did similarly infected susceptible animals[2]. This may be attributable to the replication of virus in leukocytes. In infected monkeys, virus was frequently recovered from buffy coat cells and from lymphatic tissues[3]. The role of leukocytes in enhanced infection is further supported by the observation that dengue replicates readily in cultures of peripheral blood leukocytes (PBL) prepared from immune simian or human donors, but poorly or not at all in leukocytes from non-immune hosts[4–6]. Studies on the immunological specificity of this phenomenon have been hindered by the requirement either for expensive experimental hosts (monkeys) or for human donors with chronologically defined dengue infections. Here we describe the *in vitro* enhancement of dengue infection in PBL by antibody. This system provides a provisional model for DSS in young infants during primary dengue infections[7,8].

Dengue virus, type 2 (strain 16681) (D2V) propagated in a continuous rhesus kidney cell line, LLC-MK2, was used for all *in vitro* infections[9]. D2V seeds contained approximately 10^7 plaque-forming units (PFU) per ml.

Dengue antibodies were obtained from man, monkey, mouse and rabbit. Serum was collected from naturally infected humans, or raised in monkeys by bleeding animals one or more months after a single subcutaneous injection of one of four prototype tissue culture passaged dengue viruses[9]. This regularly induced infection with the production of antibodies whose serological characteristics have been described[10]. In mice, antibodies were raised by a standard immunising schedule, using prototype mouse adapted dengue strains[11]. Antibodies were obtained in ascitic fluids induced by sarcoma 180 cells[12]. In rabbits, dengue antibodies were raised as described by DeMadrid and Porterfield[13].

PBL were collected from humans, *Macaca mulatta*, *Macaca irus*, New Zealand rabbits, Duncan Hartley guinea pigs and several mouse strains. Sera from each leukocyte donor failed to neutralise dengue 1, 2, 3 and 4 viruses when measured at a 1:10 dilution in the LLC-MK2 assay[9]. PBL were separated from erythrocytes using dextran T-250 (refs 4–6) or by isopyknic centrifugation on Ficoll-Hypaque[14]. Viable cells were adjusted to either 1 or 1.5×10^6 mononuclear leukocytes per ml in RPMI-1640 supplemented with 10% heat-inactivated (56 °C for 30 min) foetal calf serum (FCS), 20 mM HEPES, 0.02% $NaHCO_3$, 2 mM glutamine and 200 U ml^{-1} pencillin and 200 $\mu g\ ml^{-1}$ streptomycin. In some experiments heat-inactivated autologous or pooled normal monkey serum was substituted for FCS.

Dengue virus at a multiplicity of infection (MOI) of 0.1–0.01, was added to PBL suspensions containing various concentrations of dengue antiserum and to control cultures without dengue antiserum. Below a MOI of 0.001, infection did not usually occur. At first, virus, serum and PBL were incubated for 1 h at 37 °C, cell suspensions were washed twice in 50 volumes of Hanks' BSS then resuspended in medium at 1×10^6 cells per ml. Cells were incubated in screw-capped glass or plastic vials at 37 °C. Later, when

Fig. 1 Dengue 2 virus titres in cultures of normal rhesus peripheral blood leukocytes (PBL) in 20 paired comparisons, with (●) and without (○) anti-dengue 4. D2V was added to all cultures at MOI of 0.2–0.05. Virus was not removed by washing. To one half of cultures a single lot of anti-dengue 4 was added at a final dilution of 1:30. Control cultures were incubated with 1:30 autologous serum or pooled normal monkey serum. Mean plaque forming units were calculated from three 1-ounce LLC-MK2 bottles; averages of means are plotted ± s.e.m. The *t* test for paired data was performed using the square roots of mean plaque counts.

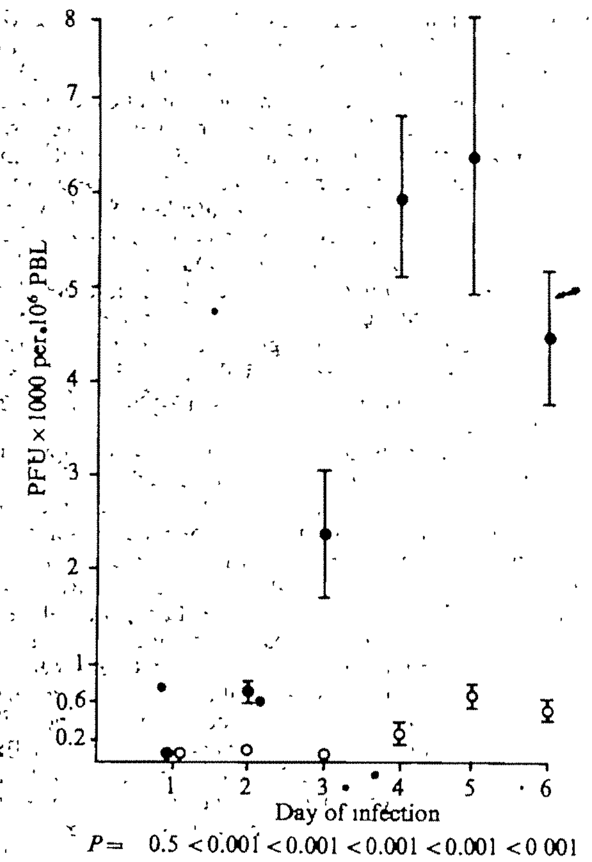

Table 1 Dengue 2 virus infection enhancement activity of serial 10-fold dilutions of anti-dengue sera raised in man, monkey, mouse and rabbit

Antibody specificity	Antibody donor species	PBL donor species	Reciprocal of titre: Against D2V HI	Reciprocal of titre: Against D2V PRNT	Reciprocal of titre: Against homologous virus* PRNT	PFU $\frac{\text{serum}}{\text{control}}$ at indicated dilution† 10^{-1}	10^{-2}	10^{-3}	10^{-4}

*Serial four-fold dilutions of serum were tested against 5–40 (PFU) of homologous virus in a LLC-MK$_2$ plaque assay. Tests involved haemagglutination–inhibition (HI) or a plaque reduction neutralisation test (PRNT).

†Ratio between PFU on day 4 of rhesus PBL cultures inoculated with D2V (MOI = 0.1) plus anti-dengue (serum) divided by PFU in control cultures. Significant differences ($P < 0.05$) are shown in italics.

‡Serum described by De Madrid and Porterfield[13]. Tested in human PBL and virus in day 3 cultures compared.

§Serum of G. Caron Sr. (ref. 15).

it was established that input dengue virus decayed to below detectable levels at 48 h, the washing step was omitted[8]. Virus was assayed on LLC-MK2 monolayers by a plaque method[9]. Infection enhancement was defined as a significant increase in plaque counts observed in antibody-containing cultures compared with appropriate control groups (*t* test).

Comparative D2V growth observed in 20 paired experiments using rhesus PBL is shown in Fig. 1. In *M. mulatta* (rhesus monkey) or *M. irus* PBL cultures, virus titres were maximal after 72–120 h of culture but in human PBL peak virus growth occurred between 48 and 72 h. The enhancement potencies of selected dengue 1, 2, 3 or 4 antisera prepared in various vertebrate species are illustrated in Table 1. For each serum, neutralising antibody titres against homologous and dengue 2 viruses measured in LLC-MK2 cells are compared with D2V infection enhancing titres in PBL. Anti-dengue 1, 3 and 4 sera raised in man, monkeys, rabbits or mice produced a similar degree of D2V infection enhancement in monkey or human PBL over a broad dilution range. Monkey anti-dengue 2, with a homologous 50% plaque reduction neutralisation titre of 1 : 1280, neutralised D2V in PBL cultures at 1 : 100 but when diluted to and above the neutralisation end point, enhanced infection. Infection enhancement titres with homologous antisera were usually 20–100-fold greater than neutralisation titres; those in heterologous sera were usually 50–500-fold higher than the D2V neutralisation titre.

Over a period of 3 yr, PBL from 40 non-immune humans of all ages, from 25 *M. mulatta* and 22 *M. irus* have demonstrated D2V enhancement, but PBL obtained from two adult New Zealand rabbits, two guinea pigs and from two adult mice of each of eight strains (Swiss Webster, AKR, TO, DBA/TO, $C_{57}Bl_{10}$, Balb C, C_3H and DBA_2) failed to support replication in the presence of dengue 1–4 antibodies.

We have obtained evidence that the leukocyte supporting dengue replication *in vitro* is a mononuclear phagocyte (unpublished results). Thus, enhancement of dengue virus infection may be a special case of the opsonisation phenomenon Non-neutralising antibody presumably provides a specific molecular 'ride' for an infectious dengue virion into the interior of a receptive phagocytic cell. It is well established that mononuclear phagocytes may serve as a genetically controlled determinant of viral pathogenicity, may be the initial site of viral replication, and may be a vehicle for systemic spread of and definitive host for viruses[16]. The failure of mouse, guinea pig and rabbit PBL to support dengue virus replication correlates with the insusceptibility of these species to dengue virus infection by the peripheral route[17] and may provide yet another example of pathogenicity determined by the ability of a virus to replicate in phagocytic cells. Mononuclear phagocytes are thought to be the only cells supporting replication in several viral infections, including Aleutian disease of mink[18]. Of particular interest to our report is the speculation that disease infection of monocytes results from the internalisation of virus-aitibody complexes[18].

If it is assumed that the right type and amount of dengue antibodies can increase the number of dengue-infected leukocytes *in vivo* and if enhanced cellular infection relates directly to disease severity, then the unusual age distribution of DSS in infants can be easily explained by the *in vitro* model described here. DSS is rarely seen in the first 3 months of life, then incidence rates rapidly increase, peak at 8 months and wane to low levels at 12 months (ref. 7). This suggests that in man as in PBL cultures, high concentrations of maternal dengue antibody may neutralise invading virus and protect the infant, but that after several months as antibody levels fall, infection enhancing activity predominates. In time this activity is lost.

The observation of antibody-enhanced virus infection in primate leukocytes is apparently new. Antibody enhancement of virus plaques, however, is well established in several systems. Hawkes and Lafferty noted enhanced plaque production when Murray Valley encephalitis virus (MVE) and rabbitpox viruses were inoculated on chick embryo fibroblast (CEF) monolayers in the presence of high dilutions of homotypic antisera[19]. Infection was mediated by avian IgG antibody and was completed within 30 min after virus-antibody mixtures were added to cell sheets. Mammalian antisera, although similar in potency, did not enhance. This unexplained result resembles a phenomenon described by Kjellén and Schlesinger[20]. In their study, mixtures of vesicular stomatitis virus (VSV) plus diluted anti-VSV inoculated on CEF, resulted in titres 10–1,000-fold higher than when the same mixtures were applied to a continuous cell line. We found that CEF contain large numbers of phagocytic cells. Hence, enhancement of plaques on CEF and perhaps some instances of 'persistence' of virus infectivity in high dilutions of antisera may be earlier descriptions of the phenomenon reported here. In a related experiment, Azuma observed enhanced interferon production in mouse macrophages incubated with mixtures of Newcastle disease virus (NDV) and anti-NDV at dilutions above the neutralisation endpoint[21]. Virus replication was not measured, but interferon production was mediated by IgG, independent of complement, and required an active Fc terminal.

These reports suggest that enhanced viral infection of phagocytic cells by non-neutralising antibody may be a rather general biological phenomenon. This possibility should be explored, particularly with viruses which exist in antigenically related groups.

We are now identifying immunoglobulin(s) mediating infection in PBL, studying the conditions which affect the reproducibility of *in vitro* antibody-mediated infection enhancement and the mechanism of infection of leukocytes by antibody-virus complexes. The availability of a simple system in which to elicit antibody-enhanced leukocyte infection may clarify the role of dengue-infected leukocytes in human pathogenic reactions.

We thank Mary Henderson and Ravithat Putvatana for technical assistance and Dr J. S. Porterfield for rabbit anti-dengue 3. The NICHHD supported this study.

Colchicine inhibits phosphatidylinositol turnover induced in lymphocytes by concavalin A

RECENTLY colchicine has been shown to affect various membrane properties such as the lateral mobility of receptors and other surface membrane markers and the agglutination of different cell types. Many of the described phenomena also involve concanavalin A (con A); for example, phagocytosis by rabbit polymorphonuclear leukocytes (PMNs) leads to a selective depletion of con A binding sites which is prevented by colchicine[1], con A inhibition of lymphocyte immunoglobulin receptor capping is reversed by colchicine[2–4] and con A-induced aggregation of PMNs, fibroblasts and hepatoma cells is inhibited by colchicine[5–7]. In addition to these effects on membrane properties, colchicine also has been shown to inhibit con A-induced lymphocyte transformation at an early stage in the sequence of events leading to thymidine incorporation and blast transformation[8,9]. These various considerations led us to determine if colchicine could alter phosphatidylinositol (PI) turnover in lymphocytes since it is known that increased PI turnover is an early event induced by con A and other mitogenic lectins[10–12].

Table 1 shows that colchicine inhibits both unstimulated and con A-stimulated ^{3}H-inositol incorporation into PI in a dose-dependent manner. At a concentration of 10^{-6} M the drug inhibited the con A increase in incorporation by 40% to 66%. In other experiments (data not shown) 3×10^{-7} M colchicine caused slight but insignificant inhibition while at concentrations of 10^{-7} M or below it had no discernible effect. Colchicine also inhibited inositol incorporation into PI in unstimulated cells although to a lesser degree than when con A was also present. At a concentration of 10^{-6} M colchicine inhibited this basal incorporation in two out of four experiments (experiments 1 and 2, $P<0.01$ and 0.1 respectively, Student's *t* test). At higher concentrations inhibition was both more pronounced and more consistent. Lumicolchicine was studied in one experiment only. At the concentrations used (10^{-6} M and 10^{-5} M) it had no effect on either basal or con A-stimulated inositol incorporation (data not shown).

While the results in Table 1 are very clear neither the mechanism by which colchicine inhibits inositol incorporation into PI nor the possible significance of this observation are immediately obvious. With respect to mechanism, it is well established that colchicine binds to tubulin and thereby prevents the formation of microtubules. It is possible, therefore, that an intact microtubule system is required for phosphatidylinositol turnover to occur. But it has been known for several years that colchicine also binds to particulate fractions in several cell types[13–16] and that in the brain and thyroid gland, at least, the characteristics of this binding are indistinguishable from those of colchicine binding to tubulin. In addition, freeze-etch electron microscopy has shown that colchicine impairs the mobility of constituents of the alveolar membranes from *Tetrahymena pyriformis*[17], presumably without altering microtubules. We favour the hypothesis that colchicine inhibits inositol incorporation through a direct interaction with tubulin or tubulin-like protein in membranes. It should be noted that this distinction between a colchicine action on microtubules or on membrane-bound protein may soon become irrevelent since there is increasing evidence of a very close association between microtubules and membranes. In rabbit ovarian granulosa cells, for example, microtubules are seen perpendicular to and directly beneath con A caps while fluorescein-labelled colchicine is localised to the cap region[18]. Similarly, Berlin and his colleagues have recently applied the technique of resonance energy transfer between fluorescent chromophores to demonstrate a close association between tubulin and membrane components in rabbit polymorphonuclear leukocytes[19,20].

Another possible explanation for the present results, namely that colchicine directly affects an enzyme or enzymes involved in PI turnover, seems unlikely since colchicine has been shown not to affect the enzymatic activity of a soluble PI phosphodiesterase purified from hog thyroid gland[21]. It is of considerable interest, nonetheless, that this phospholipase C-type enzyme, which forms cyclic inositol phosphate as one of its products, has been shown to be associated with tubulin[21,22]. Finally, it should be mentioned that the trivial explanation, inhibition by colchicine of con A binding, has been eliminated by other investigators[8].

Before considering the relevance of the present observations it is necessary to consider the significance of increased inositol incorporation into PI. It has been known for many years that numerous stimuli cause the increased incorporation of both phosphate and inositol into phosphatidylinositol (for review, see refs 23–25). In almost all tissues this incorporation reflects the turnover of the phosphorylinositol portion of the PI molecule rather than *de novo* synthesis. The enzyme initially activated by the stimuli which lead to PI turnover is of the phospholipase C type and is capable of forming D-myoinositol 1,2-cyclic phosphate as one of its water-soluble products[26,27]. Four years ago Michell and Lapetina suggested that this compound acts as an intracellular second messenger[27]. Increased PI turnover occurs almost immediately after the addition of con A or other

Table 1 Effects of concanavalin A and colchicine on ^{3}H-inositol incorporation into PI

Additions		Incorporation (counts per 10 min ± s.d.) Expt 1	Expt 2	Expt 3	Expt 4
—		1,005±44	679±34	1,212±56	1,962±198
Colchicine	10^{-4} M	823±130	358±41	751±54	1,191±42
Colchicine	10^{-6} M	910±49	485±56	1,159±58	1,450±193
Colchicine	10^{-8} M	854±21	540±83	1,258±73	2,039±153
Con A	20 µg ml^{-1}	1,707±77	1,129±12	2,860±196	3,581±166
Con A+colchicine	10^{-4} M	1,089±59	555±56	1,131±37	1,860±48
Con A+colchicine	10^{-6} M	1,200±180	767±71	1,599±17	2,250±26
Con A+colchicine	10^{-8} M	1,273±160	829±74	1,893±113	2,740±212

Four to five × 10^6 human peripheral lymphocytes isolated by density gradient centrifugation were incubated in triplicate in 1.0 ml Eagle's minimum essential medium containing 10% foetal calf serum with or without colchicine for 30 min at 37 °C. Con A and ^{3}H-inositol (approximately 1 µCi) were added and the incubation continued for 100 min after which the cells were pelleted and washed twice with medium. After addition of 7.5 ml chloroform–methanol (1:2) the cells were sonicated. 2.5 ml each of H_2O and chloroform were then added and the samples left overnight. Following centrifugation the chloroform phase was dried in scintillation vials, the residue dissolved in scintillation solution and the ^{3}H content determined in a liquid scintillation counter. The ^{3}H was shown to be localised to the PI fraction by ascending chromatography using silica gel loaded paper and both basic and acidic solvents. In preliminary experiments con A-enhanced ^{3}H-inositol incorporation into PI at concentrations of 2.5–20 µg ml^{-1}. 20 µg ml^{-1} con A was used in subsequent experiments since it produced the greatest enhancement without causing any cytotoxicity as determined by Erythrocin B exclusion.

mitogenic, but not non-mitogenic, lectins to lymphocytes and continues for as long as the lectin is present[10,11]. It has been proposed that this enhanced PI turnover is an essential step in the mechanism of lymphocyte activation. We consider that the present demonstration of colchicine inhibition of PI turnover both explains the recent observation[8,9] that colchicine inhibits concanavalin A-induced lymphocyte transformation at an early stage and also provides additional strong support for the hypothesis that increased PI turnover is required for lymphocyte transformation to occur.

The significance of the present observation with respect to colchicine effects on lateral mobility within membranes and cell agglutination is difficult to assess at present. Both phagocytosis, which initiates movement within membranes[1,28], and anti-immunoglobulin antisera are stimuli which increase PI turnover in PMNs[29–31] and lymphocytes[12] respectively. It is certainly possible that membrane changes influencing mobility occur simultaneously with or as a later result of this increased PI turnover and that colchicine alters movement by its effect on this parameter.

In summary, colchicine has been found to inhibit both basal and concanavalin A-stimulated incorporation of ^{3}H-inositol into phosphatidylinositol. We consider this effect explains the early inhibition by colchicine of con A-induced thymidine incorporation into lymphocytes and has possible relevance for colchicine effects on membrane mobility and agglutination. It will be important to determine if this newly described action of colchicine occurs in cell types other than lymphocytes and if it is shared by other microtubule-active agents.

Asymmetrical distribution of microvilli in cytochalasin B-induced pseudocleavage of mouse oocytes

CYTOCHALASIN B, a fungal alkaloid first described by Carter[1], has diverse effects on cultured cells, including inhibition of morphogenetic and movement processes, and interference with hormone mediated cellular response[2]. It also induces various cultured mammalian cells to segregate the nucleus into an evagination of the plasma membrane which occasionally breaks away from the cell body[3]. Although some of the biological effects of cytochalasin B have been attributed to the disruption of microfilamentous structures found in cells, the mechanism of action of the drug remains unclear[4]. We have found that mouse oocytes cultured in the presence of cytochalasin B divide into two compartments; a process we called 'pseudocleavage'[5]. We now report, using scanning electron microscopy, that although one of the oocyte compartments is covered with microvilli, the other is smooth. This suggests that cytochalasin B triggers a redistribution of cell surface elements in the mouse oocyte.

Approximately 15% of mouse oocytes cultured for 16 h in medium containing cytochalasin B (CCB, 5 µg ml^{-1}) underwent pseudocleavage (Fig. 1*a* and *d*). This percentage was increased several-fold by the addition of db cyclic AMP (0.2 mM) to the medium[6] or by using oocytes which failed to resume meiosis when cultured for 3 h in medium without CCB (Fig. 2). The latter experiments show that exogenous db cyclic AMP is not required for CCB-induced pseudocleavage.

To compare the topography of normal and pseudocleaved oocytes, isolated mouse oocytes were cultured in the presence of either db cyclic AMP (0.2 mM) alone or db cyclic AMP (0.2 mM) and CCB (5 μg ml^{-1}) for 16 h, then fixed and processed for scanning electron microscopy. The surface of oocytes cultured in the presence of db cyclic AMP alone was uniformly covered with microvilli (Fig. 1*b* and *c*), resembling that of oocytes cultured without db cyclic AMP. On the other hand, the surface of one of the two compartments resulting from pseudocleavage was covered with microvilli, while the other was comparatively smooth (Fig. 1*e* and *f*).

Because microvilli are uniformly distributed on the surface of mouse oocytes cultured in the presence or absence of db cyclic AMP, pseudocleavage apparently involves extensive topographical reorganisation of the oocyte. Although the mechanism of action of CCB is not clear[1], we suggest that the surface asymmetry observed here is due to interaction of CCB with the oocyte's cortical contractile apparatus[10]. In this connection, several investigators have suggested that peripheral membrane

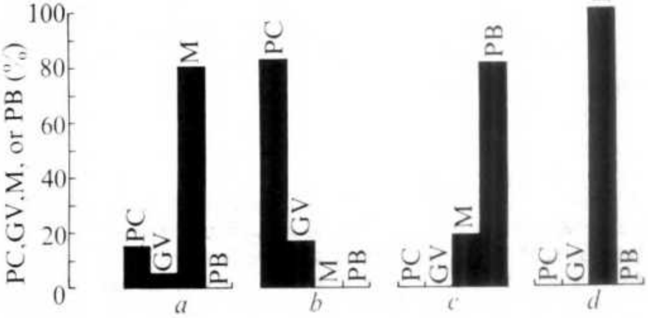

Fig. 2 Analysis of oocyte behaviour in different culture conditions. In all cases oocytes were cultured for 16 h then scored microscopically as pseudocleaved (PC), germinal vesicle (GV), metaphase I (M), or polar body (PB) oocytes. *a*, oocytes cultured continuously in the presence of CCB (5 μg ml^{-1}). *b–d*, oocytes were cultured in medium for 3 h, then those retaining an intact GV were transferred to medium containing CCB (5 μg ml^{-1}) (*b*), and oocytes which had undergone GV breakdown were transferred either to medium (*c*) or to medium containing CCB (5 μg ml^{-1}) (*d*). Each sample contained 50 or more oocytes.

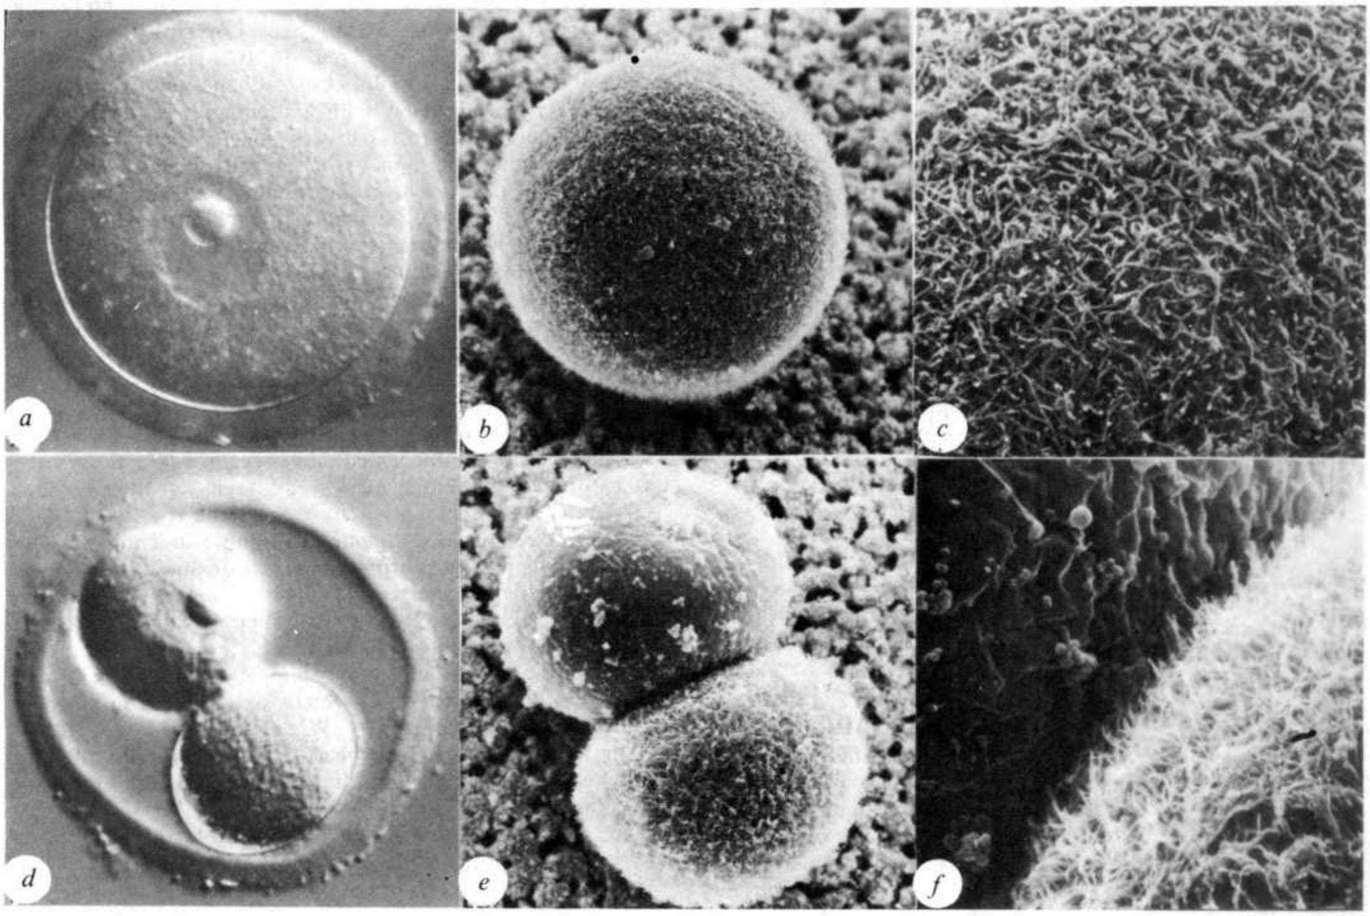

Fig. 1 Photomicrographs of mouse oocytes after *in vitro* culture. Oocytes were obtained by puncturing ovaries dissected from adult (8–12 weeks old) virgin female Swiss mice (CD-1, Charles River)[6]. Oocytes containing an intact germinal vesicle (GV) and free of cumulus cells were collected and washed in a chemically defined medium[7] and cultured in this medium under paraffin oil at 37 °C in a humidified atmosphere of 5% CO_2 in air. Approximately 85% of the oocytes underwent GV breakdown within 3 h and, of these, approximately 80% subsequently emitted polar bodies. In the presence of db cyclic AMP (dbcAMP, 0.2 mM) <5% of the oocytes resumed meiosis, as shown by the retention of an intact GV and diffuse chromatin even after 16 h (refs 8 and 9). Air-dried chromosome spreads[11] of cultured oocytes confirmed that the oocytes were arrested in the dictyate stage of meiosis. *a*, *d*, Light microscopy of live oocytes cultured for 5 h with either dbcAMP (0.2 mM) (*a*) or dbcAMP (0.2 mM) and CCB (5 μg ml^{-1}) (*d*). Light microscopy was performed using a Zeiss Photomicroscope II equipped with Nomarski differential-interference optics (*a*, ×690; *d*, ×650). *b*, *c*, *e*, *f*, scanning electron microscopy of fixed oocytes cultured for 16 h with either dbcAMP (0.2 mM) (*b*, *c*) or dbcAMP (0.2 mM) and CCB (5 μg ml^{-1}) (*e*, *f*). Oocytes were fixed with 2% buffered glutaraldehyde and zona pellucidae were removed by brief treatment with pronase (0.5%). Oocytes were collected on polylysine-coated silver membrane filters (0.8 μm porosity, Flotronics) by gentle suction, post-fixed with 1% buffered OsO_4 for 30 min at 4 °C, washed with buffer, dehydrated through a graded series of acetones, and critical point dried out of liquid CO_2. Filters were mounted on aluminium studs, coated with gold and palladium in a sputtering device (Techniques Inc.), and examined in an ETEC Autoscan scanning electron microscope (*b*, ×690; *c*, ×5600; *e*, ×900; *f*, ×5400).

components, such as actin and tubulin, influence the surface properties of cells[11–13]. Sundqvist and Ehrnst[14] have reported that exposure of several types of cultured cells to CCB resulted in an asymmetrical redistribution of microfilaments and cell surface elements. Pseudocleavage may represent an analogous response to CCB by the oocyte.

It is interesting, in view of our results, that other investigators have observed a pronounced asymmetrical distribution of microvilli over individual blastomeres during early mammalian embryogenesis[15,16]. The changes in surface organisation seem to represent a very early morphogenetic event in the embryo. CCB-induced pseudocleavage may represent an aberrant induction of events that would normally occur later in development.

Malignant transformation of rat embryo fibroblasts by herpes simplex virus types 1 and 2 at suboptimal temperature

HERPES SIMPLEX VIRUS (HSV) transforms cultured mammalian cells in three systems, involving (1) ultraviolet-irradiated virus[1–4], (2) increased incubation temperature[5,6] and (3) temperature-sensitive mutants[7,8]. Malignant transformation by HSV has been demonstrated for hamster, rat and mouse cells, using three systems[4,8–12]. We now report a further system, involving the use of a suboptimal temperature. This method is relatively convenient and seems to be applicable to various rat cell lines.

Sprague-Dawley rat single embryo cells (REF-1-76) were derived from a single clone, and grown as described before[12,13]. The cells were fibroblasts as shown in Fig. 1*a*. The normal REF-1-76 cells were established and propagated in tissue culture and so far they have not revealed any variability in the tests used in our laboratory in various tissue culture passages, even individual ones.

Three HSV strains, HSV type 1-Thea, HSV type 2-Müller and HSV type 2-HG-52, were propagated on human fibroblast cells and titred by a plaque assay[21,14]. The REF monolayer cultures in the 5th tissue culture passage were infected with HSV-1 or 2 at a multiplicity of infection (MOI) of 5 plaque-forming units (PFU) per cell. After 1 h of incubation at 37 °C the infected cells were shifted down to a suboptimal temperature of 20 °C. The cells were incubated for 1 h at 37 °C, washed five times with Hanks' solution, refed with conditioned medium[12] and divided into two parts. One part was incubated at 37 °C and the second part was shifted down to a suboptimal incubation temperature of 20 °C. Parallel cultures were mock-infected and incubated in the same way as the infected cultures and served as a control. Infected cells developed a typically HSV-induced cytopathic effect (CPE) and were destroyed when incubated at 37 °C.

Ninety per cent of the cells survived this incubation at 20 °C. The floating cells were collected by low-speed centrifugation (800g at 4 °C for 10 min), and transferred by trypsinisation to cell culture bottles. The appearance of floating cells seems to have been due to proliferating cells, which after treatment with 0.25% trypsin at 25 °C and seeding for the next passage in tissue culture lost their floating property and grew in monolayers. The monolayers and floating cells were then shifted separately up to 37 °C and maintained at this temperature. Two weeks later new cell colony formation was observed in the case of the floating cells which had been seeded and subsequently incubated at 37 °C. Transformation efficiency was approximately one colony per 10^5 original floating cells, corresponding to the formation of one colony per 1×10^6 HSV-infected rat embryo fibroblast cells. In contrast, the monolayer cells developed a typically HSV CPE and completely degenerated.

Mock-infected control cultures survived our procedure without forming foci and without producing floating cells. The new cell colonies were morphologically different from each other and different from the control cultures (Table 1). The new cells were either epithelia-like (Fig. 1*b*) or spindle-like (Fig. 1*c*), as reported for HSV-transformed REF cells[7,12]. Some clones were isolated by being picked from foci of colonies which had originated from floating cells and become established in tissue culture. As Table 1 shows, HSV-1-Thea was used for transformation of the isolated cell clone REF-T-20; HSV-2-Müller was used for REF-T-20-2, and HSV-2-HG-52 was used for REF-T-20-3. Two of the isolated HSV-transformed clones formed infectious virus after three to five subpassages and then lysed. The other isolated clones were stable in tissue culture and did not produce infectious HSV (clones 1, 2 and 3 in Table 1). The plating efficiency of normal and transformed cell clones, determined by standard procedures[15], was two or three times greater than that of the original, normal REF cells (Table 1). Using published procedures[16], we also found that the modal chromosome number of the transformed cell clones was greater than 42, which is the modal number of primary rat cells (Table 1). When the extent of colony formation in soft agar was measured[17], both the spindle-like transformed cell clones grew in soft agar, but the epithelia-like clone did not (Table 1).

The capacity of the isolated HSV-transformed clones to

Microbiological Research Establishment

Restriction Endonucleases

The following high quality preparations, which are suitable for genetic manipulation experiments, can be supplied from stock. They are stored in 50% glycerol at —20° and remain stable in this state for several months.

Restriction enzyme Eco RI

From **E. coli** RY13 (Minimum Quantity 10^4 units* @ £200), an exonuclease free preparation. Specific activity $> 10^5$U/mg protein.

Restriction enzyme Hind III

From **H. influenzae** Rd exo⁻ (Minimum Quantity 10^4 units* @ £250), an exonuclease and Hind II-free preparation. Specific activity $> 5 \times 10^4$U/mg protein.

Restriction enzyme Hpa I

From **H. parainfluenzae** (Minimum Quantity 10^4 units* @ £250), an exonuclease and Hpa II-free preparation. Specific activity $> 5 \times 10^4$U/mg protein.

* 1 unit is the amount of enzyme digesting 1 microgram of lambda DNA in 1 hour at 37°.

We have also prepared Bam-HI, Blu I, Bst I, Hae II, Hae III, Hind II, Taq YI, Xam I, Xba I, Xma I, exonuclease III, nuclease (**S. aureus**), DNA ligase (**E. coli**) and several others to order. Please enquire for further details.

The three listed products are offered at the quoted sterling prices, which remain firm for 3 months, subject to availability. Prices include packing in wet ice and delivery on UK orders which are subject to VAT at ruling rates. Overseas orders are subject to transport charges at cost.

For listed items please send your official order and delivery instructions.

For a further list of products, including bacterial cell pastes write to the Microbial Products Section, Microbiological Research Establishment, Porton, Salisbury, SP4 0JG, Wiltshire, UK.

To us, BS.3202 is a lot of hot air.

The only authoritative specification for fume cupboard face velocities is BS.3202, Recommendations on Laboratory Furniture and Fittings.

Under Section 3.203, Table 6 gives these recommended air velocities:

Type A	Fume cupboards in schools	6-12 m/min
Type B	Fume cupboards in academic and general industrial laboratories	12-30 m/min
Type C	Fume cupboards for special requirements involving toxic hazard	30-60 m/min

This standard ensures reasonable extraction through any fume cupboard, irrespective of its design or performance.

So why try and better it?

Well, one reason is that the higher the face velocity, the more hot air the laboratory loses. So fume cupboards that can operate safely at lower face velocities reduce heating costs significantly.

Which is exactly what happens with our Airflow range of fume cupboards.

Unique in design, with patented features, they are the practical result of sound engineering and accepted aero-dynamic principles. Their streamlined entrance shapes and air foil sills minimise turbulence to such an extent that they operate safely and more efficiently at 20 m/min than conventional cupboards working at 30 m/min.

So, because they work at lower face velocities, Morgan and Grundy Airflow fume cupboards eliminate turbulence, give better containment, make working conditions more comfortable and reduce the cost of heating the laboratory.

After all that, it won't come as any surprise to learn that Morgan and Grundy are specialists in the science of fume extraction and have the widest range of fume cupboards in Europe.

And that's not hot air, either.

*No. of tumours per no. of animals inoculated.

induce tumours in rats was evaluated. Newborn Sprague–Dawley rats (a closed but not strictly inbred colony), 1–2 d old, were inoculated with either normal or transformed REF cells, using 1×10^6 to 1×10^8 cells per rat. Animals were observed at least twice weekly for the development of palpable tumours at the site of inoculation. Table 1 shows that the two spindle-like transformed cell lines were highly tumorigenic in syngeneic animals. The induced tumours grew very rapidly and induced metastases in the lung. Histopathologically, the tumours were immature spindle-cell sarcomas. No regression of tumour growth was observed. The tumours could be transplanted successfully directly from animal to animal, or could be explanted and grown in tissue culture. Such cell cultures had the same morphological characteristics as the cells originally inoculated.

The detection of HSV antigens in the isolated cell clones and cell lines derived from the tumours was investigated by the indirect method of immunofluorescence, using hyperimmune rabbit antisera. The *in vitro* transformed cell clones with spindle-like morphology showed cytoplasmic HSV immunofluorescence. In contrast, the epithelia-like cell clone showed very weak fluorescence (Table 2). Cells derived from the tumours also exhibited HSV cytoplasmic immunofluorescence comparable with that of the original *in vitro* transformed cells. The isolated transformed cell clones were checked for resistance against HSV-superinfection. Monolayers of 5×10^5 cells from each clone were infected with 1×10^2, 1×10^3 and 1×10^4 PFU of HSV-1-Thea or HSV-2-Muller and overlaid with conditioned medium containing 0.5% carboxylmethyl-cellulose as described previously[13,14]. After 3 d of incubation at 37 °C in 5% CO_2 the cultures were fixed with 5% formaldehyde in phosphate-buffered saline and stained with 1% crystal violet and virus plaques were counted (Table 2). The spindle-like transformed cells, in contrast to normal and epithelia-like transformed cells, were completely resistant to superinfection with HSV types 1 and 2 in these conditions. The superinfectability of the epithalial cell clone was considerably reduced, compared with REF cells, usually by a factor 10 against HSV-1 and 10^2 against HSV-2.

Table 2 Detection of HSV-antigens in HSV-transformed and normal rat embryo fibroblast cells and sensitivity to superinfection with HSV types 1 and 2

*Petri dishes contained 5×10^5 cells.

RNA-directed DNA polymerase[15,16] was assayed to investigate the possible presence of oncorna viruses in the transformed cell clones, the tumour material and cell lines derived from the tumours (manuscript in preparation). The standard mixed culture cytopathogenicity test with XC cells[17] showed that in all cases, including cell lines derived from rat tumour biopsies, C-type virus particles were not detectable. Transformation at suboptimal temperature was repeated with two independently isolated rat embryo fibroblast cell cultures in three independent experiments and gave similar results in all cases.

In conclusion, we have shown that rat embryo fibroblasts inoculated with HSV-1 or 2 were transformed when the cells had been incubated at the suboptimal temperature of 20 °C for the first 3 weeks after infection. The transformed cell clones with spindle-like morphology were highly tumorigenic. In all control experiments the mock-infected cultures showed 20% plating efficiency and the modal chromosome number was 42. The cultures did not grow in soft agar and did not induce tumours in syngeneic animals. The mechanism of transformation at suboptimal temperature remains unclear and it is open to question whether or not the presence of part of the HSV genome is required for the maintenance of the transformed state.

This work was supported in part by the Deutsche Forschungsgemeinschaft, Sonderforschungsbereich 136. We thank Drs H. zur Hausen and H. Schulte-Holthausen for HSV-1-Thea and HSV-2 Müller; Dr F. Deinhardt for interest and for HSV-2-HG-52, and Drs A. Fried and C. H. Schröder for helpful discussions.

Secretion of hCG-α subunit and hCG by HeLa strains

IN recent letters[1,2], we have independently reported seemingly different secretion patterns of human chorionic gonadotropin (hCG) and its alpha (hCG-α) and beta (hCG-β) subunits by certain HeLa strains. These letters were further discussed in an article in News and Views[3]. Ghosh and Cox[1] found that HeLa 65 and HeLa 71 secreted a product with activity in an 'hCG-β' immunoassay (detecting hCG and/or hCG-β), and that this secretion was greatly stimulated by butyrate; hCG-α was not measured. Lieblich *et al.*[2] reported that HeLa CCL 2, 2.1 and 2.2 secreted very large quantities of hCG-α but no detectable amounts of hCG or hCG-β (<0.2 ng ml^{-1}). Two questions were raised: what was the nature of the immunoactive material in the hCG-β assay, and could the differences between the two laboratories be attributed to the known variability among HeLa strains? We have collaborated in an attempt to answer these questions, and we confirmed strain differences in hCG-α secretion in HeLa cells.

HeLa 65 and HeLa 71 were grown in increasing concentrations of sodium butyrate at New York University, and the media were analysed for hCG, hCG-β and hCG-α at the National Institutes of Health. In separate, specific radioimmunoassays (RIA), we have identified the 'hCG-β' immunoactivity as complete hCG; no free hCG-β was found (<1 ng ml^{-1}). Both HeLa strains secreted much larger quantities of free hCG-α than complete hCG (Table 1), but not sufficient hCG-α to produce significant cross reaction in the hCG RIA. Sodium butyrate stimulated both HeLa strains to increase markedly the secretion of both proteins, with the secretion of hCG-α far in excess of hCG. Although the relative stimulation by butyrate of hCG and hCG-α were within an order of magnitude (~100–500-fold), the absolute levels of hCG-α secretion exceeded complete hCG by 15-fold in HeLa 65 and 500-fold in HeLa 71. These differences between HeLa 65 and HeLa 71 in basal and butyrate-stimulated secretion of hCG and hCG-α, and the previously reported[2] differences among HeLa 2, 2.1 and 2.2 in basal hCG-α secretion may be functional counterparts of the well-described karyotypic differences among strains of HeLa.

Table 1 Basal and butyrate-stimulated secretion* of hCG-α subunit and hCG in two HeLa strains

	Butyrate concentration (mM)	Cell no. ($\times 10^{-6}$)	hCG (pmol per 10^6 cells per day)	hCG-α (pmol per 10^6 cells per day)
HeLa 65	0	17	0.01	<0.03
	1	11	0.6	2.0
	5	2.2	1.1	16
HeLa 71	0	22	0.02	15
	1	8.2	0.4	430
	5	0.3	3.0	1,450

*HeLa cells grown for 3 days in Waymouth's medium containing 10% foetal calf serum with additions of sodium butyrate as shown.

We have tested butyrate stimulation of another cell line producing α subunit ectopically. Preliminary studies in ChaGo (ref. 4), derived from a primary carcinoma of the lung, also show significant butyrate stimulation of hCG-α secretion rates. Demonstration of butyrate stimulation in a second ectopic protein-producing cell line underlines the potential of this reagent in the study of biosynthetic mechanisms.

Effects of immunisation against luteinising hormone releasing hormone on reproduction of the marmoset monkey *Callithrix jacchus*

LUTEINISING hormone releasing hormone (LHRH) is a decapeptide secreted by the hypothalamus and transported through the hypophysial portal system to the anterior pituitary gland where it acts to stimulate gonadotrophin release[1]. Selective neutralisation of this releasing factor by specific antibodies has been achieved in rodents[2–4], but there has been no report of similar work on primates. Immunisation against hypothalamic releasing hormones is a potentially suitable method for selective control of the secretion of anterior pituitary hormones. In particular, interference with LHRH release might make possible a new approach to contraception. We describe here how antibodies to LHRH were raised in the marmoset, *Callithrix jacchus*, and outline the subsequent effects on gonadal activity and pituitary function.

Ten adult marmosets, five male and five female, were immunised with synthetic LHRH conjugated to bovine serum albumin (BSA) using the carbodiimide technique[5]. Each animal received eight intradermal injections of the conjugate emulsified in Freund's adjuvant (FCA), followed by *Bordetella pertussis* vaccine as an additional adjuvant. Four further animals, two male and two female, were injected with BSA alone in FCA, together with *B. pertussis* vaccine, and served as controls. Each animal received a booster injection approximately 10 weeks after primary immunisation.

Heparinised blood samples were collected once a week from the femoral vein, centrifuged immediately and plasma was stored at −20 °C for subsequent determination of hormone and antibody levels. Testicular and uterine dimensions were also measured once weekly, using calipers. Progesterone, LH, and testosterone were measured by radioimmunoassay techniques described elsewhere[6–8]. The presence of antibody to LHRH was assessed by measuring the percentage binding of approximately 10 pg radio-iodinated LHRH by plasma at a dilution of 1 : 500.

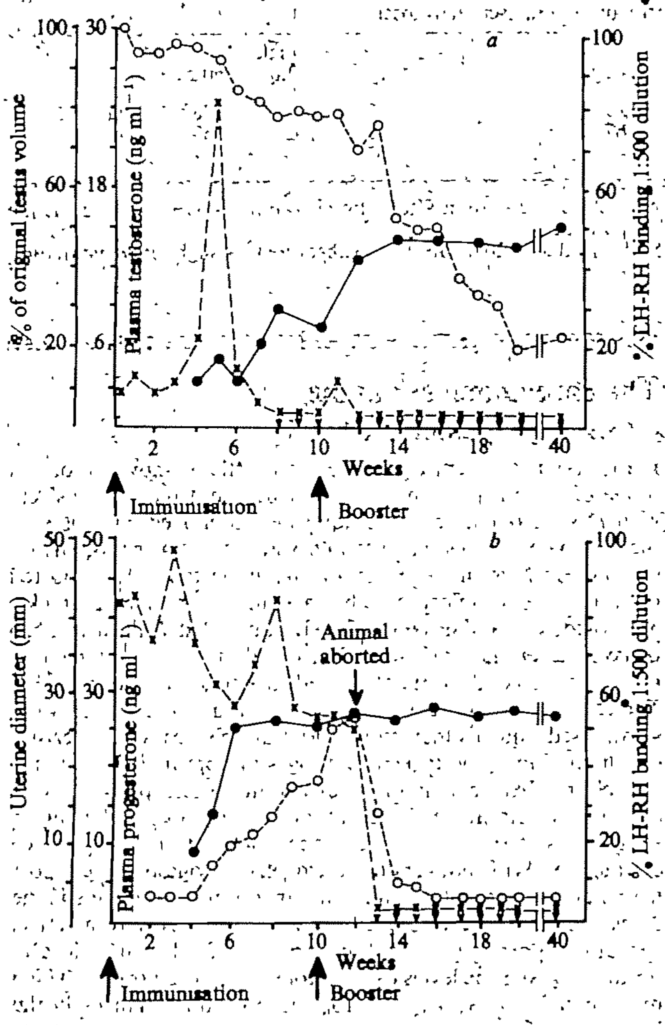

Fig. 1 Effects of immunisation against LHRH in the marmoset. *a*, Testosterone concentration (×), testis volume (○), and antibody titre (●) in a male; *b*, progesterone concentration (×), uterine diameter (○) and antibody titre (●) in a female. Arrows indicate undetectable.

No antibodies to LHRH were produced by the control animals and their gonadal activity was normal. Although all LH-RH-immunised animals produced antibodies, in four cases the titres were low (< 15% binding).

Of the six animals which developed high antibody titres (47–57% binding) all three males showed marked testicular atrophy and suppression of testosterone secretion, while all females developed inactive ovaries and became acyclic. Figure 1 illustrates the effects of immunisation against LHRH in one male and one female marmoset. In the male (Fig. 1*a*) antibody titres increased gradually during the first 10 weeks, but plasma testosterone levels were not depressed until after the booster injection, when the concentration of antibodies increased markedly. Plasma testosterone then decreased to undetectable levels (< 1 ng ml^{-1}) and the testes became softer and smaller, eventually shrinking to less than 25% of their original volume.

The female (Fig. 1*b*) was about 2 weeks pregnant at the time of immunisation and showed a more rapid build up of antibody titres during the following 6 weeks, while pregnancy continued normally. The antibody titre had reached a maximum by week 8 and the booster produced no further increase. Progesterone then began to decrease, dropping rapidly at week 12 to undetectable levels as the animal aborted. Progesterone concentrations were minimal (< 5 ng ml^{-1}) for up to 40 weeks after immunisation, showing that ovulation had ceased.

Basal LH levels in normal marmosets fluctuate around the limit of sensitivity of the LH assay (20 ng ml^{-1} LHRP-1 equivalent). Consequently, it was not possible to detect any decrease in LH concentrations after immunisation, and these results have been omitted from this report.

Histological sections of the control testes showed normal spermatogenesis, but in the three males with high levels of antibody (52–55% binding) there was marked involution of the seminiferous tubules, and spermatogenesis was severely impaired (Table 1). Interstitial cells were greatly reduced in size and contained condensed nuclei. Although seminiferous tubules in animals with low antibody titres (< 15% binding) were also reduced in size, they were considerably larger than the tubules in animals with high antibody titres, and spermatogenesis had not been affected. Ovaries in female marmosets with high antibody titres (47–57% binding) were much reduced in size, and although follicular development could be seen there was no luteal tissue. Ovaries in females with low antibody titres (< 15% binding) were not significantly reduced in size, and contained both follicular and luteal tissue (Table 1).

The effect of immunisation on the response of the pituitary to exogenous LHRH was also studied. Plasma LH levels were measured immediately before, and 45 min after intramuscular injections of various doses of LHRH (4 μg, 10 μg and 50 μg) to animals 40 weeks after immunisation (Table 2). Animals with high antibody titres showed a much reduced response at all doses compared with animals with low antibody titres, and with controls. A dose response relationship was demonstrated by high titre animals, whereas animals with low antibody titres showed a maximal response to all three doses of LHRH Even in animals with high antibody titres that had been immunised for 40 weeks and were infertile, the pituitary gonadotrophs were still able to respond to the releasing hormone. An LHRH test on immunised animals may provide a better

Table 1 Ovarian and seminiferous tubule measurements in control and immunised marmosets

Group	Tubule diameter (μm) Mean ± s.d.	Ovarian size length (mm) × breadth (mm) Mean ± s.d.
Control	279.5±21.7	61.4±2.2
LHRH-immunised high titres	132.2±9.9	12.4±1.7
LHRH-immunised low titres	245.1±21.1	47.6±3.9

In each group 20 tubule diameters from two males were measured. The mean tubular diameter in each group of immunised animals was significantly smaller than that in control animals ($P < 0.001$; Student's t test). Laparotomy was performed on two females in each group and the right ovaries were measured across their longest and shortest axes. The product of these two measurements was taken as a rough indication of ovarian size. Ovaries in animals with high antibody titres were significantly smaller than those in the controls ($P < 0.001$; Student's t test). There was no significant difference in ovarian size between control animals and animals with low antibody titres.

Table 2 Response to LHRH in control and immunised marmosets

	Male			Female		
	4μg	10μg	50μg	4μg	10μg	50μg
LHRH-immunised high titre (6)	0†	14	23*	7*	22	28*
LHRH-immunised low titre (4)	79	63*	67	72	68*	63*
Control (2)	83	—	—	87*	—	—

Plasma LH concentrations (ng ml^{-1} LHRP-1 equivalent) were measured before and 45 min after administration of LHRH, and the net increase (Δ LH) is shown. The total number of animals used is indicated in parentheses.

* Pre-injection levels were undetectable (< 20 ng ml^{-1}) and to calculate Δ LH, a value of 20 ng ml^{-1} was substituted. A slight underestimation of Δ LH values has therefore resulted.

† Both pre- and post-injection levels were undetectable.

indication of the effectiveness of immunisation than measurement of antibody titres.

These results demonstrate that immunisation against LHRH is an effective way of suppressing gonadal activity in the marmoset. Although the necessity for Freund's adjuvant and the rather drastic effects of complete inhibition of LHRH preclude its acceptability as a method of human fertility control at the moment, it may still be possible to develop a new approach to contraception by LHRH inhibition, achieved either immunologically, or by the use of competitive LHRH antagonists Total suppression of the testis would be necessary in the male to ensure infertility, and this would probably be undesirable In the female, however, it may be possible to suppress the ovary to a level which would effectively prevent ovulation, but would still allow some follicular development and oestrogen secretion.

We thank Dr E. Vogl of Hoechst Ltd for LHRH, Dr. J. Uilenbroek for LH antiserum, and Dr H. M. Fraser for advice. We also thank Professor R. V. Short for criticism of the manuscript, and Mr F. J. Burden for care and maintenance of the animals.

The carcinogen ethionine elevates progesterone levels

ETHIONINE is a potent carcinogen, but little is known about its mode of action. It is known that it does not react extensively with DNA[1]. It may be an ubiquitous carcinogen, as it is synthesised by *Escherichia coli*[2] and several other microorganisms, so studies of its mode of action are important. We reported recently a novel effect of ethionine in the immature chick[3]. The oviducts of chicks previously stimulated with oestrogen behaved after the administration of ethionine as if they had received a second stimulation with oestrogen or progestin[4-6]. The egg white proteins, ovalbumin and conalbumin were synthesised and distinct morphological changes, characteristic of stimulation by oestrogen or progestin appeared. It was thus not clear whether ethionine (or its metabolic product) was affecting steroid hormone receptors[7] directly, or interferring in some way with steroid hormone metabolism to produce elevated levels of endogenous oestrogen or progestin. We report here that ethionine or its sulphoxide are unique in inducing in the chick oviduct the effects cited above; analogues were inactive. We also report that the administration of ethionine elevates serum progesterone levels over 10-fold, to a concentration which may be sufficient to account for the profound changes in the immature oviduct.

We used the procedure developed in the laboratories of O'Malley[8,9] and Schimke[4,5,10]. Oestrogen administration to the immature chicks results in extensive cytodifferentiation of the primitive oviduct and synthesis of cell-specific proteins. Ovalbumin synthesis is first detected approximately 18 h after oestrogen stimulation, and after 7–10 d of daily stimulation it accounts for 50–60% of total protein synthesis (primary stimulation)[11]. Discontinuation of oestrogen administration is accompanied by a gradual loss in cell-specific protein synthesis. Ovalbumin synthesis is not detectable after 15–20 d of oestrogen

Table 1 Effect of analogues and metabolites of ethionine on induction of ovalbumin synthesis in immature chick oviduct

Treatment	^{14}C-amino acids incorporated, per mg soluble protein (c p.m. × 10^{-4})	^{14}C-amino acids incorporated into ovalbumin, per mg soluble protein (c.p.m. × 10^{-4})	Ovalbumin synthesis, % of total protein synthesis
None	1.84	ND	0
L-Ethionine	2.43	0.59	24.3
L-Ethionine sulphoxide	1.91	0.327	17
	1.57	0 062	4
L-Ethionine sulphone	1.03	ND	0
	1.19	ND	0
N-Acetyl-L-ethionine	1.42	ND	0
	1.47	ND	0
S-Propylhomocysteine	1.03	ND	0
	1.46	ND	0

Four day old chicks were injected with 1 mg of oestradiol 17-β-benzoate in sesame oil for 10 d. After a withdrawal period of 4 weeks, the chicks were injected (in groups of eight), intraperitoneally (i.p) with a 1-ml suspension, in water, of L-ethionine or its analogue and metabolites (0.25 mg per g body weight) and adenine (0 12 mg per g body weight) for 5 d. On the sixth day the animals were sacrificed, the oviducts removed, the magnum portions of the oviduct freed of adjoining tissue and cut into small pieces. The magnum explants were incubated *in vitro* in antibiotic free medium containing labelled amino acids[13] Tissue was incubated in 2 ml of medium in 25-ml Erlenmeyer flasks for 3 h. Each flask contained tissue from three oviduct magna. Ovalbumin synthesis in the magnum explant was determined by specific immunoprecipitation as described before[14-16]. L-ethionine was from Sigma, L-ethionine sulphoxide, L-ethionine sulphone and *N*-acetyl-L-ethionine were from Cyclo. *S*-propylhomocysteine was synthesised in our laboratory[17]. ND, not detected.

Table 2 Elevation of progesterone levels in immature chicks by ethionine

Treatment	Ovalbumin synthesis in oviducts, % of total protein synthesis	Serum progesterone (ng per 100 ml)	Serum 17-β oestradiol (ng per 100 ml)	Total serum cholesterol (mg per 100 ml)
None	ND	29	10	103
Ethionine + Adenine				
3 d	ND	40	8	155
4 d	6	153	7	150
5 d	16	285	3	114
Oestradiol 17-β benzoate, 2 d	35	40	448	361
Progesterone, 2 d	34	523	7	113

After 10 d of primary oestrogen stimulation chicks were withdrawn for 21 d and (in groups of eight) injected i.p. with ethionine and adenine as described for Table 1. Oestradiol or progesterone (2 mg per chick, in sesame oil) were injected intramuscularly. At the times specified, blood was collected by cardiac puncture and the separated serum was stored frozen until analysed. Analyses for progesterone[18], 17-β-oestradiol[19] and total cholesterol[20] in serum were performed by Laboratory Procedures, Upjohn. The values are the average of duplicate determinations. These experiments were repeated with another group of chicks with essentially the same results (data not shown). Ovalbumin synthesis was determined in duplicate and the values are an average. There were some variations in the time course and degree of induction of ovalbumin synthesis and progesterone by ethionine.

withdrawal (withdrawn chicks). Administration of oestrogen or progesterone[4,5] or ethionine[3] to withdrawn chicks results in rapid restoration of cell-specific protein synthesis in the chick oviduct.

To ascertain whether ethionine analogues or its metabolites had similar biological activity, we tested several related compounds. There was a rigid structural requirement for ethionine in the induction of ovalbumin synthesis. Ovalbumin synthesis produced by ethionine sulphoxide was less extensive than by ethionine (Table 1). In the rat, ethionine is metabolised to ethionine sulphoxide, *N*-acetylethionine and *N*-acetylethionine sulphoxide, but ethionine sulphoxide and *N*-acetylethionine can be converted back to ethionine[17]. In the chick the metabolism of *N*-acetylethionine seemed to be different, as it failed to induce ovalbumin synthesis. The sulphone derivative of ethionine and its propyl homologue failed to elicit the synthesis of ovalbumin.

The administration of ethionine plus adenine produced an elevation of up to 10-fold in serum progesterone levels but had no significant effect on the levels of 17-β-oestradiol (Table 2). Progesterone, unlike oestrogen, is incapable of inducing cytodifferentiation of tubular gland cells or ovalbumin synthesis in the unstimulated immature chick oviduct[4–6]. Ethionine and progesterone are similar in this respect; they produced no pronounced effects on specific protein synthesis without previous oestrogen stimulation[3]. Furthermore, there is little growth of the oviduct during secondary stimulation with ethionine, another characteristic of the administration of progestins.

Since these determinations were done by radioimmunoassay by a commercial firm (see legend to Table 2), we determined the reproducibility of the individual values. Serum samples were re-submitted for analysis after storage for 1 month at −15 °C, under different code numbers. In no case was the variation greater than 2-fold whereas the increment in progesterone level was more than 10-fold. Given the complexity of the assay and the unknown effects of storage, the values obtained may be considered valid.

The mechanism of the elevation of serum progesterone levels by ethionine is obscure, it could be the result of increased synthesis of progesterone or decreased degradation or excretion.

Cholesterol was also determined in the serum of chicks (Table 2). Increase in cholesterol synthesis in the rat is induced by the administration of several carcinogens, such as ethionine, aflatoxin, *N*-2-fluorenylacetamide and 3-methyl-4-dimethyl aminoazobenzene[21]. The effect is thought to be a loss of feedback control of synthesis by dietary cholesterol. These changes in cholesterol synthesis are observed much before the appearance of any pathological stigmata of tumours. Increased rate of cholesterol synthesis and impairment of its feedback control is also characteristic of a variety of primary and transplantable tumours[21] and lymphocytic leukaemic cells[22]. Whether the elevation in the levels of cholesterol which is a precursor of steroid hormones is causal in the elevated levels of progesterone is not known.

Elevation of the progesterone levels by the carcinogen ethionine may have far reaching implications. The importance of endocrine activity in neoplasia is well known[23]. Whether this novel effect of ethionine is unique among chemical carcinogens in producing an imbalance in hormone metabolism remains to be determined.

We thank Dr R. D. Palmiter for helpful suggestions, and the US NIH and US Energy and Research Development Administration for grants.

Sodium nitroprusside and other smooth muscle-relaxants increase cyclic GMP levels in rat ductus deferens

SMOOTH muscle tone seems to be primarily regulated by the concentration of free calcium in cytoplasm[1,2]. Several agents that cause smooth muscle contraction increase the tissue content of cyclic GMP with no significant change or only small reduction of the cyclic AMP concentration[3–7]. It has been suggested[5–7] that cyclic GMP may be casually involved in the contractile response of smooth muscle and that this nucleotide may act as a comediator with calcium to promote contraction. Several observations, however, are not consistent with this assumption. Although increases both in tissue tonus[1,2] and in the cyclic GMP level[8–10] induced by hormones and neurotransmitters are generally dependent on the presence of extracellular calcium and seem to be secondary to increased influx of calcium into the cytoplasm, the correlation between these two calcium-dependent events is poor in various tissues[10–16]. On the basis of such observations, we have suggested that cyclic GMP may act as a negative feedback inhibitor of hormonally stimulated calcium influx into cytoplasm[8,10,11]. We have studied the effects of various agents on cyclic nucleotide levels in the ductus deferens of the rat, and report here that many smooth muscle relaxants, including sodium nitroprusside (SNP), increase cyclic GMP levels in the ductus deferens.

Although several of the tested agents are more potent in vascular smooth muscle than in tissues of the visceral type of smooth muscle, the ductus deferens was used, since in this tissue the contribution of smooth muscle cells to tissue mass is higher than in most other smooth muscular tissues and the importance of extracellular calcium for hormone effects on cyclic GMP levels is well established[8–16].

SNP is a potent vasodilator[17] and causes relaxation of the potassium-depolarised ductus deferens (K.D.S., unpublished). Addition of SNP to segments of ductus deferens increased the cyclic GMP level severalfold (Table 1). When calcium was omitted from the incubation medium, basal cyclic GMP levels were decreased and the effect of acetylcholine on the cyclic GMP level was abolished, whereas the effect of SNP was still observed. In the absence of extracellular calcium, SNP (0.1 mM) increased the cyclic GMP level about 50-fold within 20 s, and a maximal increase of about 100-fold was observed after 1 min (Fig. 1). Half-maximal stimulation was caused by 10 μM SNP, and the effect on the cyclic GMP level was maximally developed with about 1 mM SNP (see Fig. 1). Cyclic AMP levels were not changed in any of these conditions.

Hydroxylamine increases the cyclic GMP level in rat cerebral cortex[20] and caused relaxation of various smooth muscular tissues including ductus deferens (K.D.S., unpublished). In our system, hydroxylamine 0.1 mM increased the cyclic GMP level of the ductus deferens 4-fold, and 20- to 30-fold in the presence and absence of extracellular calcium, respectively; cyclic AMP levels were unchanged (Table 2).

Various other smooth muscle-relaxants and antihypertensives also increased cyclic GMP levels in the rat ductus deferens when they were added in the absence of extracellular calcium (Table 3). Nitroglycerol (0.1 mM) and sodium nitrite (1 mM), agents that have been shown to increase the cyclic GMP content in other tissues[13,19,21,22], increased the cyclic GMP level of the ductus deferens about 2-fold after 3 min Furthermore, the antihypertensives diazoxide, hydralazine and minoxidil; the coronary

Table 1 Influence of extracellular Ca^{2+} on the effects of SNP and acetylcholine on rat ductus deferens cyclic GMP level

Addition	Cyclic GMP concentration (pmol per g wet weight): 2 mM Ca^{2+}	no Ca^{2+}
None (control)	56.4±5.6 (13)	10.6±1.5 (15)
Acetylcholine	163±22.6 (9)	12.7±2.1 (10)
SNP	585±79 (7)	596±39 (7)

Tissue segments were preincubated for 30 min in a balanced salt solution[18] containing 30 μM EDTA and 2 mM or no calcium chloride. Tissue was then transferred to fresh medium containing 2 mM or no Ca^{2+} as above with or without addition of 0.1 mM acetylcholine or 0.1 mM sodium nitroprusside. After 5 min of incubation, tissue was fixed, and cyclic nucleotides were extracted, purified and assayed by established methods[19]. Data are mean ±s.e.m., with the number of samples in parentheses. Cyclic AMP levels were not significantly changed in any of the above conditions.

Fig. 1 Effect of SNP on cyclic nucleotide levels in the ductus deferens. Segments of tissue were preincubated for 30 min in medium without addition of calcium. Sodium nitroprusside was then added for 3 min at the concentrations indicated on the abscissa in *a*. A time course of the response was obtained by adding 0.1 mM sodium nitroprusside for the times indicated on the abscissa in *b*. Data are mean ± s.e.m., the number of tissue samples per group was 7.

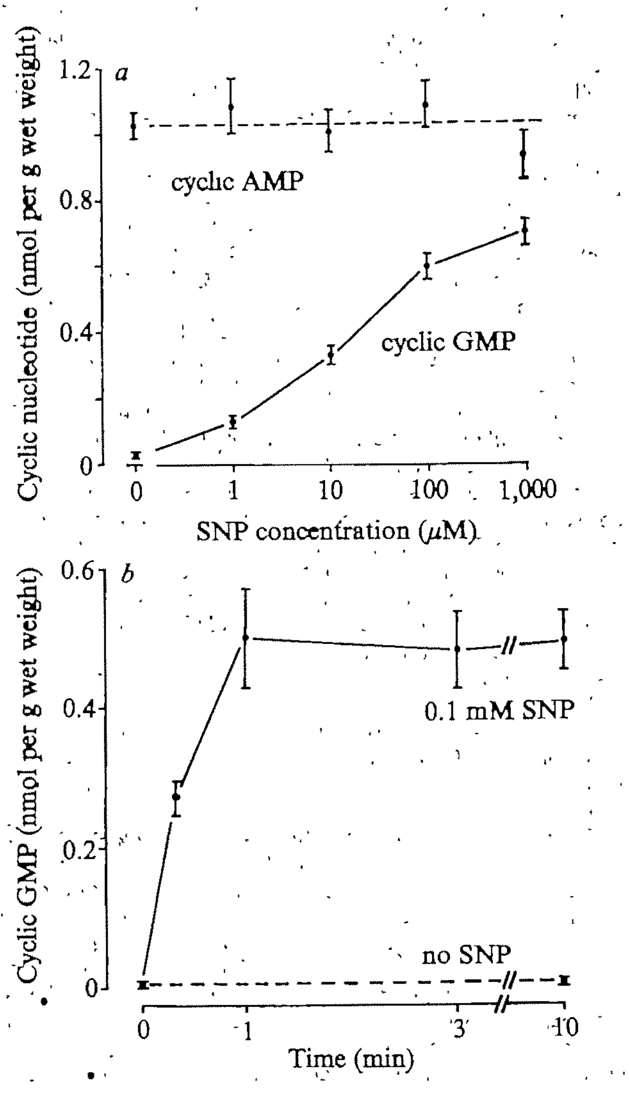

Table 2 Effect of hydroxylamine on cyclic nucleotide levels in presence and absence of Ca^{2+}

	Concentration (pmol per g wet weight) Cyclic GMP	Cyclic AMP
2 mM Ca^{2+} Control	42.8 ± 2.9 (7)	914 ± 34 (8)
Plus hydroxylamine (5 min)	177.7 ± 25.5 (8)	1002 ± 91 (8)
no Ca^{2+} Control	9.5 ± 2.2 (8)	1051 ± 88 (8)
Plus hydroxylamine (5 min)	195.4 ± 19.7 (8)	1067 ± 71 (8)
Plus hydroxylamine (10 min)	260.3 ± 25.4 (7)	970 ± 37 (5)

Segments of rat ductus deferens were preincubated for 30 min without addition of calcium. After 5 min incubation with or without 2 mM calcium, hydroxylamine (0.1 mM) was added for 5 to 10 min. Control values were not significantly changed over this period. Values are mean ± s.e.m.

artery dilators dipyridamole, prenylamine, cinnarizine, lidoflazine, perhexiline, and the methoxy derivative of verapamil (D-600), SKF-525A and chlorpromazine (0.1 mM each) each caused a 2- to 3-fold increase in the cyclic GMP level when added for 3 min to segments of ductus deferens. In contrast, the local anesthetic tetracaine, phenytoin and pentobarbital (0.1 mM each) did not change the cyclic GMP significantly (Table 3), although these agents caused relaxation of the K^+-depolarised tissue. Cyclic AMP levels were not affected by any of the above compounds.

The mechanism by which these agents increase the cyclic GMP level independently of the presence of calcium is not known. Increased cyclic GMP formation is more likely than reduced degradation of the nucleotide, as the effect of the potent phosphodiesterase inhibitor, 1-methyl-3-isobutylxanthine, on the cyclic GMP level in the ductus deferens depended on the presence of calcium whereas the effect on the cyclic AMP level was not affected by calcium[8]. Although several of the above drugs are capable of inhibiting phosphodiesterases in cell-free sytems[23], none of the agents changed the cyclic AMP level in the ductus deferens. Furthermore, SNP, sodium nitrite and hydroxylamine all stimulate guanylate cyclase from rat ductus deferens (H. Graf and G.S., in preparation).

Table 3 Effect of smooth muscle relaxing drugs on cyclic nucleotide levels

(Experimental series I)	Concentration (pmol per g wet weight) Cyclic GMP	Cyclic AMP
Control	24.6 ± 4.2 (23)	1052 ± 35 (25)
Ethanol	29.2 ± 7.5 (14)	1006 ± 59 (15)
Nitroglycerol	65.7 ± 6.9 (14)	1061 ± 61 (13)
Sodium nitrite	65.1 ± 7.0 (11)	1001 ± 81 (5)
D-600	59.9 ± 6.2 (14)	955 ± 91 (8)
Cinnarizine	67.4 ± 14.0 (8)	977 ± 91 (10)
Lidoflazine	68.6 ± 17.6 (11)	1020 ± 78 (11)
Perhexiline	55.2 ± 14.4 (8)	922 ± 76 (11)
Minoxidil	84.2 ± 17.9 (8)	996 ± 64 (12)
Hydralazine	61.9 ± 15.7 (10)	1054 ± 65 (13)
Diazoxide	57.4 ± 8.3 (10)	1128 ± 69 (11)
(Experimental series II)		
Control	5.8 ± 1.1 (8)	1025 ± 25 (7)
Prenylamine	28.9 ± 9.5 (7)	954 ± 31 (8)
Dipyridamole	36.3 ± 4.4 (7)	972 ± 50 (6)
Chlorpromazine	29.1 ± 9.3 (9)	942 ± 49 (8)
SKF-525 A	22.8 ± 4.3 (8)	896 ± 33 (7)
Tetracaine	7.7 ± 1.5 (9)	970 ± 61 (9)
Phenytoin	8.3 ± 3.3 (9)	923 ± 36 (9)
Pentobarbital	6.7 ± 2.4 (7)	958 ± 41 (7)

Segments of ductus deferens were preincubated for 30 min in buffer without addition of calcium. Drugs were then added for 3 min at a concentration of 0.1 mM and sodium nitrite at 1 mM. Ethanol (0.2%, v/v) was used as a solvent of nitroglycerol and perhexiline. Values are mean ± s.e.m., with number of samples in parentheses.

D-600, prenylamine and several other of the active drugs are known to reduce the responses of smooth muscule and other tissues to hormonal stimuli by their so-called calcium-antagonistic property[24–26]. The 8-bromo derivative of cyclic GMP exogenously applied (10^{-5} M) also reduced the contractile responses of the rat ductus deferens and other tissues to some stimuli and diminished the effect of calcium on the tonus of the K^+-depolarised ductus deferens (K.D.S., V. Kreye and G.S.). These observations together with our finding that relaxing drugs as well as contraction-producing hormones increase cyclic GMP levels support the hypothesis[8,10,11] that cyclic GMP may reduce or prevent calcium influx into the cytoplasm of smooth muscle and possibly other cells and may thereby reduce hormone-induced excitation or excitability.

Trypsin inhibits the action of tetrodotoxin on neurones

Evidence suggests that the molecules responsible for membrane excitability are proteins[1–4], but they have not been isolated in spite of considerable efforts and their identities remain unknown. Some clues have come from study of the effects of enzymes and group-specific chemicals on appropriate electrophysiological properties of the membrane[1–4]. In certain nerve and muscle cells the voltage-dependent inward currents which generate action potentials may be carried by Na^+ or Ca^{2+} (refs 5–13). Tetrodotoxin (TTX) specifically blocks the voltage-dependent inward Na^+ current in many of these cells[14], including neurones of *Aplysia*[10] and *Helix*[11] and is widely used for this reason. It also has the advantage of being a relatively simple molecule of known atomic structure[14]. But TTX has no effect on *Helix* neurones when they are isolated from the ganglia in which they are located[13]. The ganglia are first pretreated with trypsin and we wondered whether the lack of TTX-sensitivity in these preparations was due to some action of this enzyme on the TTX receptor. We have now found that exogenous trypsin modifies the TTX-binding properties of the Na channel without affecting its reversal potential or selectivity against Tris$^+$ and has no measurable effect on the Ca^{2+} channel. Because trypsin splits polypeptide chains on the carboxyl side of arginine or lysine residues[15], it seems likely that the TTX receptor contains either or both of these amino acids but that the selectivity site does not.

We have developed a simple suction pipette method with which individual nerve cell bodies can be isolated, perfused internally and voltage clamped. This method will be valuable in the study of individual cell membranes of excitable or inexcitable tissues.

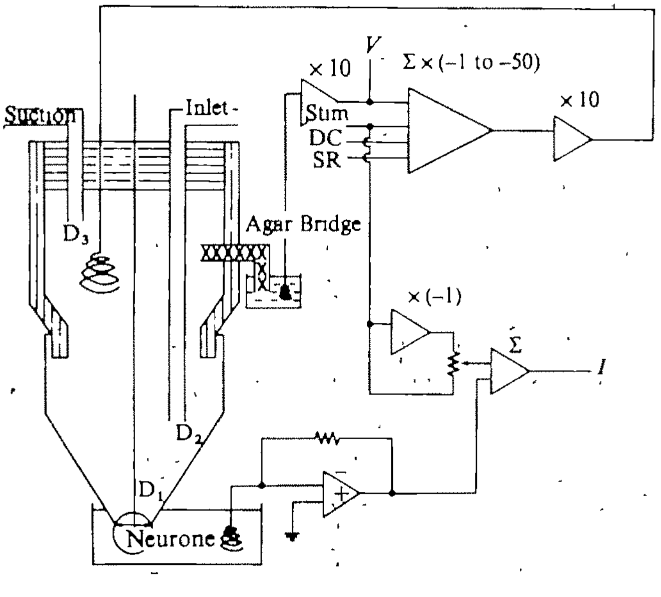

Fig. 1 Schematic of experimental setup. D$_1$ = 25 µm, D$_2$ = 500 µm, and D$_3$ = 2 mm SR, series resistance compensation. Σ is the summing amplifier used to offset the shunt resistance.

We examined neurones from the circumoesophageal ganglia of *Helix aspersa* using a suction pipette with an internal diameter of 15–30 µm (Fig. 1), filled with a solution of 50 mM K aspartate and 55 mM KH$_2$PO$_4$ adjusted to *p*H 7.4 with 28 mM Tris$^+$ base[16]. The extracellular solution bathing the neurones had the following composition: 75 mM NaCl; 5 mM KCl; 10 mM CaCl$_2$; 15 mM MgCl$_2$, and 5 mM Tris-HCl, *p*H 7.6 The neurones were exposed by stripping off the capsule of the ganglion with jeweller's forceps. A neurone with a diameter ranging from 80 to 250 µm was sucked into the tip of the pipette and isolated by rending it free from neighbouring neurones. A platinised platinum wire (5 µm tip) was then advanced into the neurone. It had a resistance of 3×10^4 Ω and was connected through an agar salt bridge and Ag AgCl wire to the voltage amplifier (Fig. 1) A reference for the voltage was also provided by a salt bridge connected to the bath, but this is not shown in Fig. 1. In these conditions and at a temperature of 18 °C we measured resting potentials of −60 mV. (after corrections for measured liquid junction potentials), input resistances of 15–20 MΩ, and action potentials with overshoots of 20–30 mV for periods averaging 6 h. Similar values were obtained when two 3 M KCl-filled micropipettes, one for passing current and the other for recording voltage, were inserted into the same neurone. These measurements indicate healthy neurones and we presume that the soma healed over at the site where it had been pulled free from its axon much the same way as cut cardiac muscle heals over.

The voltage clamp circuit included series resistance compensation[17] and a circuit for correcting the offset currents passing across the shunt resistance of 50 and 100 MΩ (ref. 18) that isolated the cell body from the extracellular solution (Fig. 1).

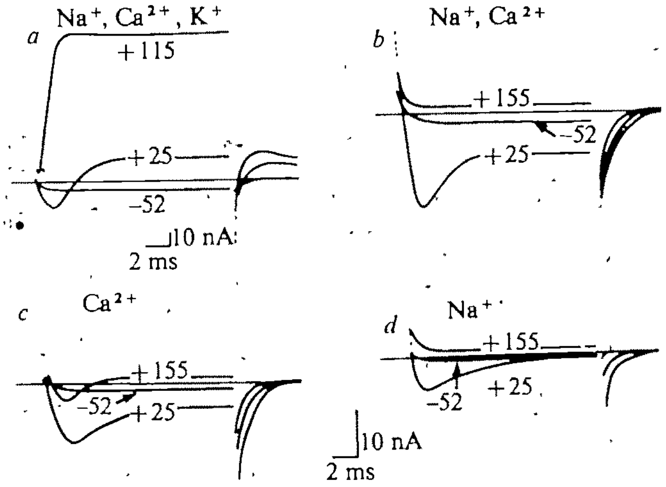

Fig. 2 Voltage clamp currents and their separation in *Helix* neurones. Holding potential, $V_H = -60$ mV. Voltage clamp potentials indicated above respective currents Note the differences in current calibration between (*a*) and (*b*), (*c*) and (*d*). *a*, Neurone perfused internally with control solution (see text). External solution contained CsCl. The voltage-dependent currents are due to Na$^+$, Ca^{2+} and K$^+$. The small depolarising step produces sustained inward current. The current tails are outward for the larger voltage steps. *b*, *c* and *d*, Current traces from a different neurone. *b*, After 20 min of internal perfusion with Cs aspartate, the voltage-dependent outward K$^+$ current is abolished. The remaining voltage-dependent currents are due to Na$^+$ and Ca^{2+}. Early current is outward at +155 mV and the persistent outward current is attributed to leakage. At +25 mV there is an early transient inward current and a later smaller persistent inward current. The tail currents are now inward at all steps and appear to recover more rapidly. *c*, Ten minutes after 3 × 10^{-6} M TTX was added to external solution Ca^{2+} current is separated Notice early inward current at +155 mV, indicating that E_{Ca} is more positive than this value Inward current at +25 mV is reduced by about 30% The Ca^{2+} current is abolished by verapamil or Co^{2+}. *d*, Same neurone as (*b*) and (*c*), 30 min after recovery from TTX and 5 min after addition of 5×10^{-6} M verapamil to the external solution. The Na$^+$ current is separated. The early current is outward at +155 mV, shows little inactivation at −52 mV, but inactivates almost completely at +25 mV. The Na$^+$ tail currents are smaller than the Ca^{2+} tail currents. The Na$^+$ current is blocked by TTX and substitution of Tris for Na$^+$ in the external solution.

The voltage clamp currents in the control solutions were elicited by voltage steps from holding potentials of −60 mV and had voltage-dependent Na$^+$, Ca^{2+} and K$^+$ components (Fig. 2*a*). They were separated from each other as follows. The K$^+$ current was blocked by substituting 110 mM Cs aspartate for the potassium salts in the control internal perfusion solution (Fig. 2*b*). We also substituted Cs$^+$ for K$^+$ in the extracellular solution. Addition of TEA to the internal or external media had no further effects. We used TTX (Sigma or Sankyo) to block the Na$^+$ current The action of TTX was dose-dependent and reversible TTX in doses of 3×10^{-7} M reduced the inward current by an average of 30% in 40 neurones (Fig 2*c*). Similar doses were also effective in *Aplysia* neurones[19]. Replacement of Na$^+$ in the external solution with Tris$^+$ had a similar effect to TTX in 20 neurones. Thus, 30% of the inward current was carried by Na^+. This Na^+ current was isolated after blocking Ca^{2+} current with verapamil (Knoll) in doses of $1–5 \times 10^{-5}$ M or by substituting Co^{2+} for Ca^{2+} (Fig. 2*d*). The Na^+ current has a transient peak and then inactivates although the time course may vary among different neurones.

After TTX or $Tris^+$ substitution for Na^+, the inward current was carried by Ca^{2+} (Fig. 2*c*). A component of the Ca^{2+} current elicited by small depolarisations showed little or no inactivation as previously reported[19]. At larger voltages the inward Ca^{2+} current also had a transient peak. The calcium was increased or decreased when extracellular calcium was doubled or halved, and reduced or abolished by when Co^{2+} was substituted for Ca^{2+} or verapamil was added. In TTX, the Ca^{2+} current was unchanged when $Tris^+$ was substituted for Na^+. Substitution of methanesulphonate ion for Cl^- had no effect on any of these currents.

Having established the presence of a TTX-sensitive Na^+ current, we tested the effects of trypsin (type III, Sigma) on this current in 20 neurones. The outward K^+ and inward Ca^{2+} currents were blocked and the inward Na^+ currents elicited by 20-mV voltage steps from −60 to +160 mV were recorded. Such Na^+ currents could be blocked by TTX or substitution of $Tris^+$ for Na^+ (Fig. 3*a*). Neurones with the inward Na^+ current separated in this way were then exposed to 0.1% trypsin for about 2–4 min. Exposure to these doses of trypsin for this period increased membrane resistance silghtly but did not affect the magnitude of the inward currents or their reversal potentials. In some instances, the time course was slightly altered. TTX now had no effect on the Na^+ current (Fig. 3*d*). But substitution of $Tris^+$ for Na^+ still blocked the inward current (Fig. 3*e*).

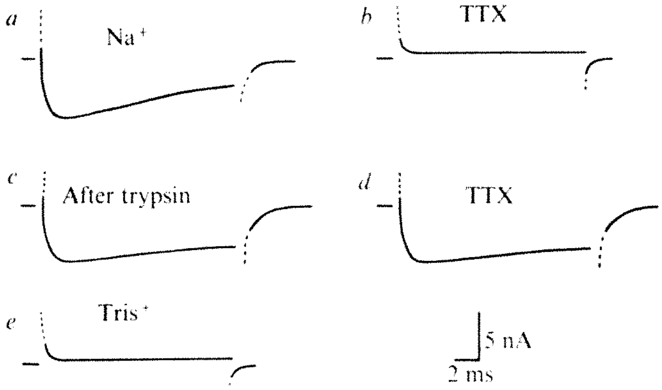

Fig. 3 Na^+ current in a *Helix* neurone, its blockage by TTX and the effects of trypsin on the Na current and the TTX blockage. $V_H = -60$ mV. All currents elicited by voltage steps to +25 mV. Internal perfusion with Cs aspartate, external solution contains CsCl (see text). Ca^{2+} currents blocked by verapamil. *a*, Control Na^+ current. *b*, After 5 min in 3×10^{-5} M TTX. Only the outward leakage current persists. *c*, After recovery in TTX-free solution for 30 min and exposure to 0.1% trypsin for 3 min. The magnitude of the inward current is unchanged but inactivates more slowly. This is not, however, a consistent finding. *d*, After 10 min exposure to 1.5×10^{-4} M TTX in trypsin-free solution. TTX no longer blocks Na^+ current. *e*, Substituion of $Tris^+$ for Na^+ in the external solution eliminates the Na^+ current leaving a small outward leakage current.

To examine whether trypsin acted on the Ca^{2+} current, we separated it from the Na^+ and K^+ currents and compared the inward currents before and after enzyme treatment. Equivalent exposures which abolished TTX-sensitivity had no effect on either calcium currents or their blockage by verapamil or Co^{2+}. Exposures of 10 min, however, reduced membrane resistance and Ca^{2+} currents as well as the TTX-insensitive Na^+ current.

Trypsin destroys the TTX-sensitivity of the neuronal membrane without affecting the magnitude and time course of the inward currents. This accounts for the absence of TTX sensitivity in snail neurones[13] pretreated with this enzyme. The action is specific since Na^+ current persists and the Ca^{2+} current is unaffected. The external application of trypsin to lobster giant axon[1], or α-chymotrypsin to squid giant axon[4], was also without effect on the membrane's electrical properties although another enzyme, Pronase, when applied internally to squid giant axon, removes Na^+ inactivation selectively[3]. If the guanidinium group of the TTX molecule blocks the Na^+ channel at the selectivity filter[20], the persistence of a TTX-insensitive inward Na^+ current with an unchanged reversal potential suggests that the selectivity filter has not been affected by trypsin. Thus, trypsin may act on the part of the channel occupied by the remainder of the TTX molecule and this portion probably contains lysine and/or arginine residues. It is also interesting that modifications of TTX at carbon positions 4 and 9, which are close to the guanidinium group, greatly reduce the potency of the toxin[21]. The lack of TTX sensitivity of some excitable cells, such as puffer fish neurones[22] and denervated skeletal muscle[23] cells, may have a similar basis.

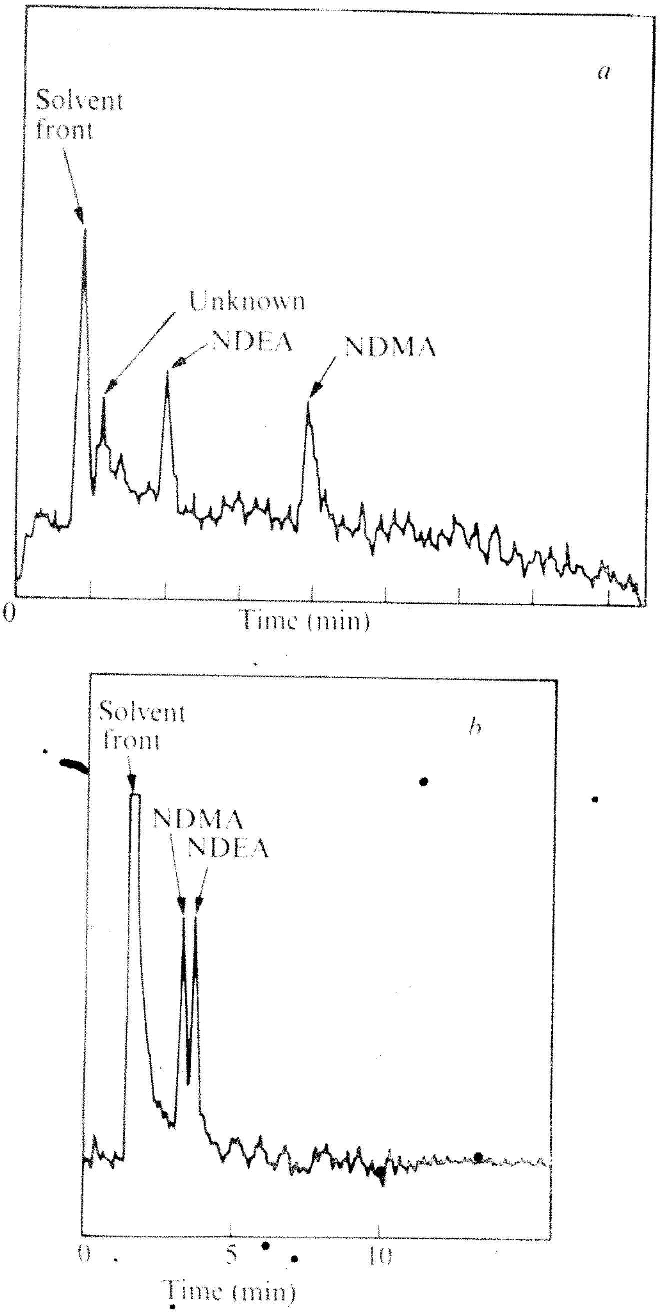
Formation *in vivo* of volatile *N*-nitrosamines in man after ingestion of cooked bacon and spinach

N-NITROSAMINES, which are thought to be causally related to human cancer[1], have been found in μg kg^{-1} concentrations in polluted air[2,3], in water[4] and in tobacco products[5]. Foodstuffs such as cooked bacon, preserved with nitrite, have long been known to contain μg kg^{-1} amounts of volatile *N*-nitrosamines formed during cooking[6]. *In vivo* formation of *N*-nitrosamines, after ingestion of suitable amine precursors and nitrite, has been demonstrated in laboratory animals[7]. *In vivo* formation in human subjects with hypoacidity, gavaged with relatively massive amounts of diphenylamine plus nitrite, has been demonstrated through detection of *N*-nitrosodiphenylamine in the stomach contents[8]. *In vivo* nitrosation after ingestion of conventional foods has not been demonstrated so far, either in animals or man. We now report *in vivo* formation of volatile *N*-nitrosamines in man after ingestion of a midday meal consisting of a bacon, spinach and tomato sandwich and beer.

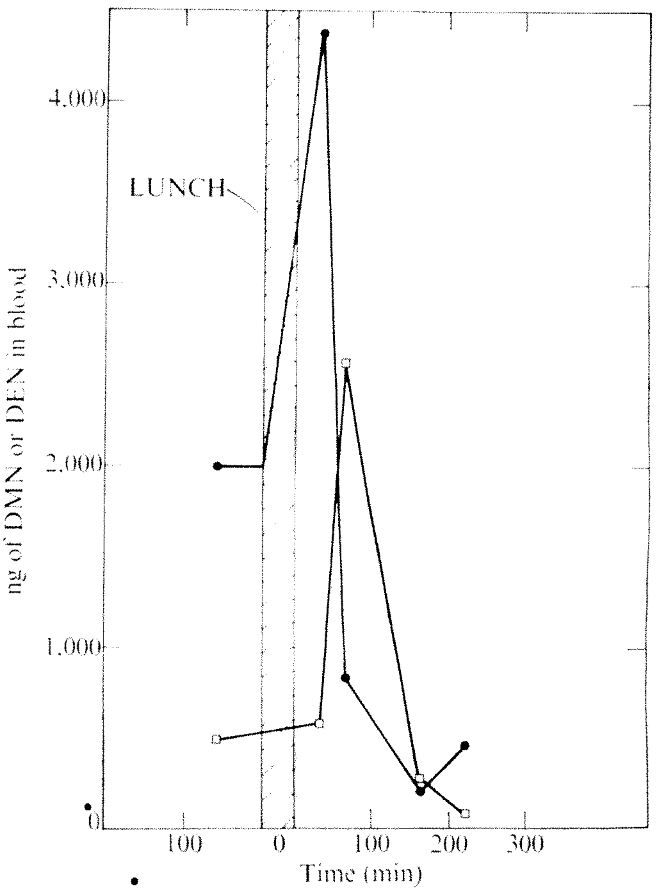
Fig. 1 *a*, High-pressure-liquid-chromatogram for a 10-µl extract of whole human blood. The TEA-HPLC was constructed[10] by combining an injector (Waters Associates, model UK6), with a high-pressure pump (Waters Associates, model 6000A) and a thermal energy analyser (Thermo Electron, model TEA-HPLC 502). A µm Porasil column was used with a 5% acetone–95% 2,3,4-trimethylpentane solvent system at a flow rate of 2 ml min^{-1}. TEA attentuation was × 2. *b*, Gas–liquid chromatogram for a 10-µl extract of whole human blood. A single-column isothermal gas chromatograph was constructed[11] from 14 feet of stainless steel tubing (outer diameter 1/8 inch), packed with 10% Carbowax 20 M on Chromasorb W, 80–100 mesh. The column temperature was 180 C, with Ar carrier gas at a flow of 25 ml min^{-1}. A thermal energy analyser (Thermo Electron, model TEA-502) was used as the detector. TEA attenuation was × 2.



Blood (20 ml) was taken on the day before the test. On the day of the test, 20 ml of blood was taken 50 min before the noon meal. Lunch consisted of 310 g of spinach, 170 g of cooked bacon, 200 g of tomatoes, 120 g of bread and 460 g of beer. One per cent of the total lunch was analysed for volatile *N*-nitrosamines. Blood samples (20 ml) were taken 35, 65, 162 and 220 min after the meal. A final control sample was taken at 1,300 min. Samples were poured immediately into liquid nitrogen. Less than 20 s elapsed between the end of collection and freezing in liquid nitrogen. Mineral oil was added to the whole blood, which was analysed for volatile *N*-nitrosamines by standard procedures[9]. Control experiments were performed by recovering *N*-nitrosodimethylamine (NDMA), *N*-nitrosodiethylamine (NDEA) and *N*-nitrosopyrrolidine (NPYRR) at the 0.4-µg kg^{-1} level (0.4 p.p.b.) from whole human blood (obtained from a blood bank). The blood from the bank contained no voltaile *N*-nitrosamines.

The meal contained preformed NDMA and NPYRR. The total amount of preformed NDMA ingested was 1,600 ng. Identification of NDMA and NDEA was confirmed using both TEA-GLC and TEA-HPLC. Figure 1 shows the chromatographic traces of the blood sample taken 162 min after the meal. The TEA-GLC trace shows only two peaks, those at the retention time of NDMA and NDEA. The TEA-HPLC trace shows three peaks, two eluting at the same retention time as NDMA and NDEA (note that the peak order is reversed). Furthermore, the quantities of NDMA and NDEA are identical for both the GLC and HPLC systems. As a further confirmatory step, the NDMA and NDEA peaks eluting on the HPLC were

Fig. 2 *In vivo* nitrosation in man after ingestion of bacon, spinach, tomato and beer. ●, NDMA; □, NDEA.



isolated and reconcentrated and then injected on to the GLC. The peak corresponding to NDMA on the HPLC gave only a single peak on the GLC, corresponding to NDMA. The same was true for NDEA. Given the selectivity of the TEA, evidence for the identity of volatile *N*-nitrosamines based on parallel TEA-GLC and TEA-HPLC procedures can be taken as confirmatory[10,11].

The amount of NDMA and NDEA present as a function of time in the blood (assuming total body blood is 5,640 ml) is shown in Fig. 2. Before the meal the blood contained 2,000 ng of NDMA and 510 ng of NDEA; 35 min after the meal NDMA had increased to 4,350 ng and NDEA to 570 ng, and 65 min after the meal, NDMA had fallen to 860 ng while NDEA had increased to 2,600 ng. At 162 min, both had decreased below the levels observed before the meal. At 1,300 min there was 760 ng of NDMA in the blood; NDEA was not present. NPYRR was not detected in the blood either before or after the meal.

These amounts of NDMA in human blood imply that the compound was being formed *in vivo* in quantities greater than those present before the meal. The total amount of NDMA in the body may be considerably in excess of that reported here because we assumed that all NDMA was taken up in the blood alone—an appreciable amount may have been exhaled or absorbed in various tissues. NDEA was not found in the food, but it was formed *in vivo* after the meal. It is interesting that the content of NDEA was maximal after the concentration of NDMA had reached its maximum. Our experiments were carried out three times, giving similar results for NDMA, although the actual measurements differed in each case. NDEA was detected in only one of the three experiments. The source of the background NDMA in the blood is unknown; no background was observed if the volunteer had eaten a bland low nitrate–nitrite, high ascorbate diet for the previous 24 h.

The experiments reported here, although simple, demonstrate conclusively that *N*-nitrosamines can be formed *in vivo* in man after ingestion of conventional foodstuffs.

The ability routinely to detect nitrosation *in vivo* should make possible realistic tests of putative environmental carcinogens.

Ferritinaemia in cancer

SMALL amounts of ferritin are found in serum in normal and pathological states[1,2], usually at levels directly related to the amount of tissue storage iron[3,4]. This relationship, however, does not hold in many cancers where grossly elevated levels can occur without a corresponding increase in iron stores[5–9]. These latter findings suggest a possible use of ferritinaemia in cancer diagnosis, but the value of this test has not been clearly established. Such use is complicated by the multiple potential sources of the serum ferritin which could affect its type as well as its amount. Much of the ferritin in cancer sera may reflect increased iron stores arising from chronic anaemia or from transfusions in treated patients. Some may also come from nonspecific tissue damage. The high levels of ferritin synthesis in some cancer cells[10] and the presence in serum of isoferritins characteristic of some cancer and foetal tissues[11,12], however, suggest that much of the ferritin may come directly from cancer cells. If so, selective quantitation of these isoferritins may provide specificity in possible serodiagnosis. The multiple isoferritins found in most human tissues seem to be hybrid molecules composed of different proportions of two subunit types[13]. One type predominates in liver and spleen isoferritins, and the other in the more acidic isoferritins in heart, tumours and HeLa cells[14]. Different isoferritin populations can be distinguished immunologically, apparently on the basis of their subunit composition[14,15]. Ferritin is usually assayed by immunological methods, with crystalline liver or spleen ferritins as immunising antigens and reference standards. These ferritins consist almost entirely of the liver-type subunit[15]. Consequently, most assays based on these ferritins have only a low reactivity for the more acidic 'carcinofoetal' isoferritins which may contain less than 20% of the liver-type subunit[11,15]. We have, therefore, tested a variety of cancer sera and compared the apparent levels of ferritin given by a standard 'liver-type' assay with levels given by an assay whose specificity is directed against the more acidic isoferritins[15]. We report here preliminary evidence that the latter type of assay may significantly improve the usefulness of ferritinaemia as a tumour marker.

Serum samples from untreated patients with various histologically confirmed malignancies were provided by Dr Elliot Alpert, Massachusetts General Hospital, Boston, Mass. The leukaemic sera were obtained from New England Medical Center, Boston. The samples were not graded according to the stage of disease or other pathological disorders. The levels of ferritin in these sera were estimated by two radioimmunoassays (RIA). One RIA reacts preferentially with liver-type isoferritins, the other with the more acidic isoferritins characteristic of heart and HeLa cells[15]. Antibodies for the 'liver-type' RIA were raised in rabbits against crystalline human liver ferritin consisting of approximately 90% of the liver-type subunit. Antibodies for the 'HeLa-type' RIA were developed against HeLa ferritin (>80% heart-type subunit). Before use, the anti-HeLa antiserum was absorbed with a natural apoferritin preparation (>95% liver-type subunit) to restrict its specificity to sites determined by the heart-type subunit[15].

The apparent level of the serum ferritin from 8 out of 12 different cancers was substantially higher when estimated with the 'HeLa-type' than with the 'liver-type' assay (Table 1). In most cases, the ratio of the values given by the two assays (HeLa–liver) was between 2 and 5. These ratios are markedly different from those obtained in non-malignant conditions, such as iron overload, where the ratio was less than 0.1. This differential indicates that the ferritin in these cancer sera contained substantially higher proportions of the heart-type subunit than the serum ferritins from iron overload. This conclusion must also apply even in cases where the apparent level given by the 'HeLa-type' RIA was slightly lower than that given by the 'liver-type' RIA (for example, cases 4, 21).

Table 1 Serum ferritin levels (ng ml^{-1})

Case no.	Diagnosis	Liver-type	HeLa-type	Ratio HeLa/liver
1	Normal	77±48	ND	—
2	Hemochromatosis	5000	190	0.04
3	Hemochromatosis	950	ND	—
4	Teratoblastoma	1550	1000	0.6
5	Glioma	130	ND	—
6	Ovarian carcinoma	62	430	7.1
7	Breast cancer	205	500	2.4
8	Breast cancer	330	800	2.4
9	Breast cancer	190	350	1.8
10	Breast cancer	50	140	2.8
11	Pancreatic carcinoma	600	1900	3.1
12	Pancreatic carcinoma	320	600	1.9
13	Pancreatic carcinoma	460	500	1.1
14	Hepatoma	560	850	1.5
15	Gall bladder carcinoma	550	2700	5.0
16	Colon carconoma	220	1500	6.7
17	Stomach carcinoma	750	1750	2.4
18	Stomach carcinoma	118	235	2.0
19	Stomach carcinoma	550	1050	1.9
20	Lung carcinoma	630	1750	2.8
21	Multiple myeloma	2630	1350	0.5
22	Acute lymphoblastic leukaemia	3800	165	0.04
23	Acute lymphoblastic leukaemia	34670	130	0.004
24	Acute myeloblastic leukaemia	1675	ND	—
25	Acute myeloblastic leukaemia	1866	135	0.07
26	Pancreatitis	1170	740	0.6

Values given as ND were below the minimum detectable level at 100 ng ml^{-1} in the 'HeLa-type' assay. The difference in sensitivities of the two assays reflects our inability to iodinate HeLa ferritin to the same extent as liver ferritin.

Although the differential in serum ferritin levels given by the two assays holds in most cancers examined here, some, such as the leukaemias, did not conform to this general pattern. The very low HeLa–liver ratio in these samples could reflect liver-type isoferritins in the cancer cells or increased iron stores due to deficient erythropoiesis. High levels of the more acidic isoferritins have been found in untreated leukaemias[8].

The immunological differences among human isoferritins might be of value in obtaining information about serum ferritin phenotypes in various pathological states. Our results indicate that the 'HeLa-type' RIA might not only add a key element of specificity for assessing ferritinaemia in many cancer sera but might also detect abnormally high levels which might not be evident with the 'liver-type' assay (for example, cases 6, 7, 9, 16). If the more acidic isoferritins reflect high levels of secretion, rather than cell damage, their detection may prove useful in early diagnosis. It should be noted, however, that elevated levels of these isoferritins in sera are unlikely to be entirely specific for cancer. These isoferritins occur in small amounts in heart, kidney and pancreas[16] and their level in serum may increase in conditions such as myocardial infarction[5,8] and pancreatitis (case 26). More thorough studies are required to extend our preliminary observations and to correlate the type and amount of serum ferritin in cancer and other pathological states throughout the course of the disease.

We thank the American Cancer Society and NCI for a grant and the MIT Cell Culture Center for providing us with HeLa cells.

Phosphorus nuclear magnetic resonance of perfused working rat hearts

THERE are serious limitations to techniques used to correlate biochemical parameters with function in metabolically active tissues. For the perfused heart such techniques include measurement of surface NADH fluorescence[2], comparison of coronary arterial–venous composition, and biochemical analysis of intracellular metabolites from biopsy specimens. Although the latter approach has yielded critical information, it is limited because local injury prevents accurate interpretation of mechanical function. Recently ^{31}P nuclear magnetic resonance (NMR) has been used to analyse excised muscles and their acid extracts for intracellular concentrations of the sugar phosphates, glycolytic intermediates, free orthophosphates, phosphocreatine, ADP and ATP. In addition, the *p*H-dependent chemical shift of the orthophosphate resonance has been titrated[2] and used to determine the intracellular *p*H of intact muscles[3]. These muscles were neither perfused nor functioning, but we report here the assessment by ^{31}P NMR of the myocardial energy status in the working, perfused rat heart subjected to various degrees of ischaemia.

Albino Sprague–Dawley rats (200 g) were injected with 1,000 U of heparin and anaesthetised with 20 mg of pentobarbital. The hearts were excised, washed with cold perfusate and, within 3 min, perfused by means of a cannula inserted into the aorta and positioned above the aortic valve. The cannula was attached to a column 107 cm high. Left ventricular pressure was monitored by means of a catheter, 100 cm long, inserted through the left atrial appendage and mitral valve, and connected to a Statham P23Db strain gauge tranducer and a Brush 220 recorder. The perfusate was maintained at 30 °C and was bubbled continuously with pure oxygen. It contained 145 mM NaCl, 6 mM KCl, 1.3 mM $CaCl_2$, 0.4 mM $MgSO_4$, 16.7 mM glucose, 20 mM Tris-Cl (*p*H 7.4) and 1% Dextran 70.

^{31}P NMR spectra were obtained on a Nicolet TT 23 pulsed Fourier transform spectrometer interfaced to a Varian V 4412 probe. The heart was contained in a 12-mm NMR tube. Field-frequency control was obtained by locking on the deuterium signal from a 3-mm glass tube, containing pure D_2O, which was slipped into the NMR tube alongside the pulsing heart. Where desired, an external reference signal was obtained from a 1-mm capillary containing 0.2 M H_3PO_4 in 15% $HClO_4$. Typically, data was obtained using an 8K data table, a 2,000-Hz spectral width, a 2.0-s acquisition time and 1,000 transients. Probe temperature was maintained at 30 °C.

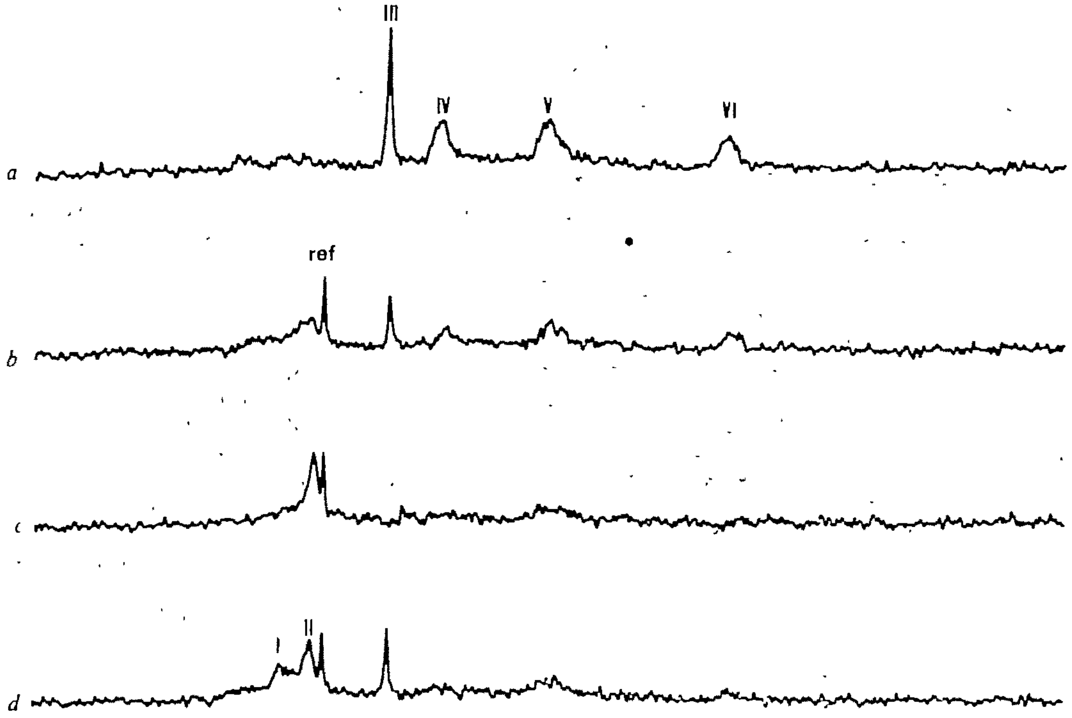

Fig. 1 ^{31}P NMR Spectra of working perfused rat hearts (40.5 MHz). *a*, Normal perfusion pressure of 107 cm H_2O. *b*, partial ischaemia, at a perfusion pressure of 43 cm H_2O Ref., Reference signal. *c*, Total ischaemia with aortic cross-clamp. *d*, Reperfusion at 107 cm H_2O. Peak assignments: I, sugar phosphates; II, orthophosphate; III, phosphocreatine; IV, γ ATP; V, αATP, VI, βATP,

Figure 1*a* shows the ^{31}P spectrum of a beating perfused rat heart in optimum conditions of perfusion. Assignments are taken from ealier work on excised muscle[2,3]. The active muscle is characterised by prominent resonances from the three phosphates of ATP and the phosphate group of phosphocreatine and only weak resonances from inorganic phosphate and sugar phosphates. When partial ischaemia was produced by reducing the perfusion column from 107 to 42 cm H_2O, the heart rate declined from 214 to 178 beats per min and left ventricular pressure declined as expected (Fig. 1*b*). The intensities of the ATP and phosphocreatine resonances decreased markedly relative to that of inorganic phosphate. Figure 1*c* shows the effect of 25 min of total ischaemia produced by cross clamping the aortic cannula. During total ischaemia the heart stopped pulsing. Neither phosphocreatine nor ATP resonances were detectable but the inorganic phosphate resonance increased markedly. With reperfusion the heart started to beat again, and the resulting ^{31}P spectrum is shown in Fig. 3*d*. Obviously, the phosphocreatine and ATP resonances increased above the ischaemic levels while the inorganic phosphate resonance decreased. Apparently, the total intensity of the phosphorus resonance decreased with time, presumably due to leakage of inorganic phosphate from the heart into the perfusate during ischaemia. The *p*H of the tissue was monitored by the chemical shift of inorganic phosphate. The results for the heart in various conditions are shown in Table 1. Intracellular *p*H decreased by 1.2 *p*H units during partial ischaemia and by a further 0.5 *p*H unit during total ischaemia.

In several experiments (spectra not shown) the linewidth of the P_i resonance tended to be greater in fully perfused heart than in either partially or totally ischaemic heart. This suggests that *p*H gradients existing in oxygenated heart are dissipated in ischaemia. During reperfusion of ischaemic heart a small signal appeared in the region expected for sugar phosphates. This may reflect a buildup of glycolytic intermediates before some critically inhibited enzymatic step.

Table 1 Intracellular *p*H measured by ^{31}P NMR

Condition	Perfusion pressure (cm H_2O)	Chemical shift (p.p.m. from H_3PO_4–$HClO_4$ reference)	*p*H
Normal	107	2.04	7.4
Partial Ischaemia	43	0.86	6.2
Total Ischaemia	0	0.46	5.7
Reperfusion	107	0.68	6.1

Thus we have explored both the energy status of a tissue and its intracellular *p*H. Biochemical data were collected in steady-state conditions and correlated well with changes in mechanical function. With minor modifications our method is applicable to liver, kidney and other perfused tissues, and we believe that it represents a useful new technique.

Cloning and expression of the flagellar hook gene on hybrid plasmids in minicells

SPECIFIC *Escherichia coli* DNA fragments carrying flagellar genes have been cloned on λ vehicles and gene expression has been studied in λ-infected ultraviolet irradiated-cells[1-4]. This work has led to the identification of several gene products involved in flagellar function. But, the structural gene for the hook subunit protein, which is one of the major flagellar components has not been identified. This gene could have been missed if it was not part of the DNA that was cloned, if it was cleaved during endonuclease treatment or if it was transcribed at such a low level that the product could not be detected in ultraviolet-irradiated cells. We report here another approach which avoids these difficulties and has enabled us to identify the region of the genome which carries genes involved in the synthesis of flagellar hook and basal structures. This result is interesting for two reasons. First, it demonstrates the general applicability of cloning techniques to the identification of any gene product in *E. coli* Second, it focuses attention on a hitherto poorly defined group of genes involved in flagellar structure and function.

Various proteins are associated with *E. coli* flagellar structure and function. The flagellar organelle seems to be composed of three sections: the filament, the hook and the basal structure[5-7]. The filament is made up of a single polypeptide subunit called flagellin with an apparent molecular weight of 53,000 (ref. 6). The hook is also composed of a single polypeptide subunit with a molecular weight of 42,000. The hook subunit is clearly distinguished from flagellin by its specific reaction with antihook subunit antiserum[7]. The flagellar filament rotates, and the hook may act as a flexible 'universal joint' connecting the filament to the basal structure. The basal structure is complex and composed of at least nine different polypeptides[8]. Other proteins involved in flagellar formation and function are localised in the cell membrane and cytoplasm[2,9].

The genes responsible for flagellar formation have been defined by genetic complementation tests, and more than 20 of them were found to map in three regions of the *E. coli* chromosome (Fig. 1). Some of these genes have regulatory functions. Thus strains that carried mutations in the *flaI* gene did not synthesis hook subunits or other flagellar component proteins[7,9]; whereas strains that carried mutations in the *flaE* gene seemed to over-produce the hook subunit protein and formed polyhooks. The *flaE* gene is not responsible for the synthesis of the hook subunit protein[7,10]. Mutants that have altered hook subunit proteins have not been found. To find the structural gene, it was necessary to use the plasmid–*E. coli* hybrid system and study the expression of genes carried by plasmids that were segregated into minicells.

Clark and Carbon[11,12] prepared a colony bank of strains

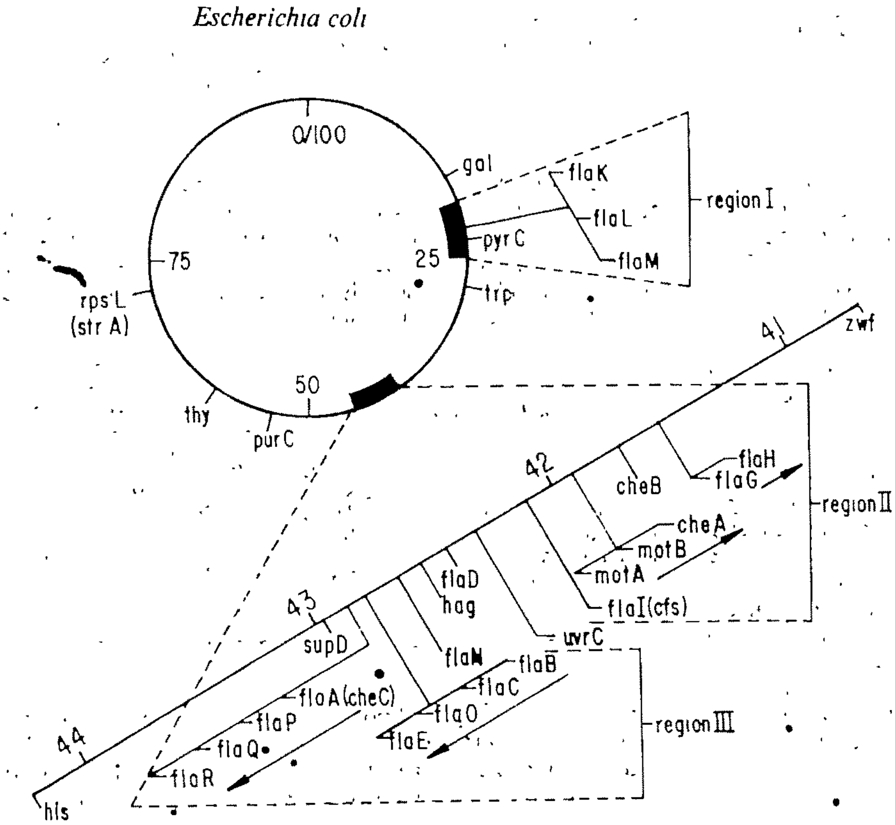

Fig. 1 The map positions of genes controlling flagellar structure and function in *E. coli*. The gene designations have been described before[8,14]. fla refers to genes that include mutation which result in strains that have no apparent flagellar structure; hag is the structural gene for the major subunit protein of the flagellar filament; mot refers to mutations that result in paralysed flagella; che includes strains that do not respond to chemotactic signals; cfs refers to a regulatory locus controlling the sensitivity of flagellar formation to cyclic AMP (ref. 7).

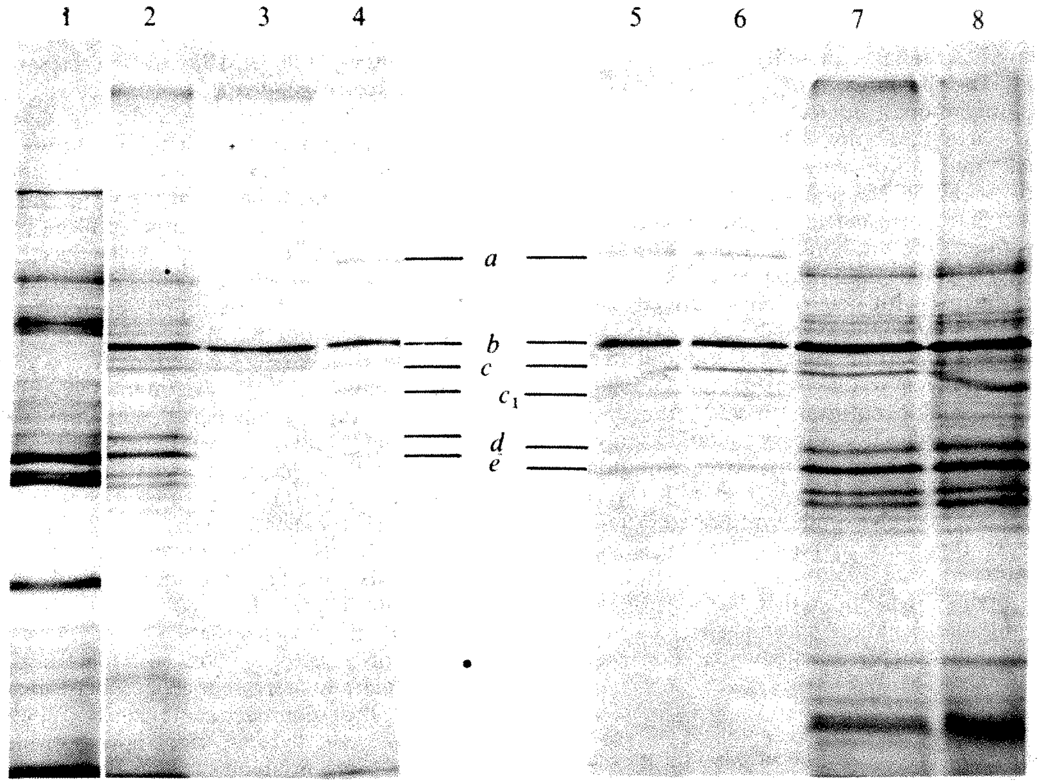

Fig. 2 Autoradiograms of SDS–acrylamide electrophoresis gels of minicells carrying hybrid plasmids. The plasmids were transferred by conjugation into minicell producing strain P678-54 (obtained from R. Sparks, University of California, San Diego). All plasmid-carrying strains were from the Clarke and Carbon collection[12]. Minicells were collected after the parent strain had been grown for 14 h in L broth and thymine (15 μg ml^{-1}) at 37 °C. The minicells were purified by differential centrifugation and sucrose gradients[13]. They were pre-incubated in M-9 minimal medium with glycerol supplemented with 19 amino acids (4 μg ml^{-1}); no methionine was added. After incubation at 37 °C for 20 min, ^{35}S-methionine (20 μCi ml^{-1}, 350 Ci mmol^{-1}) was added and incubation continued for 30 min. The minicells were collected and lysed in buffer containing 3% SDS and 0.5 M βME. Samples were heated to 100 °C for 2 min. The electrophoresis on 12 1/2% acrylamide gels has been described before[2]. In samples 5 and 8, βME was omitted. For antibody precipitation, the minicells were lysed by treatment with EDTA and lysozyme[8] and then sonicated for 2 min. The debris was removed by centrifugation for 45 min. The supernatant was dialysed, lyophilised and reconstituted, and nonradioactive hook subunit protein was added as carrier. Anti-hook subunit antibody 926 (ref. 7) was used to precipitate the protein at equivalence. The precipitate was washed twice with cold buffered saline and resuspended in lysis buffer. Sample 1, minicells with plasmid pLC 7-18 carrying *flaD*; sample 2, minicells with plasmid pLC 11-15 carrying *flaK*, *flaL* and *flaM*; sample 3, pellet after antibody precipitation of extract of minicells carrying pLC 11-15; samples 4 and 6, hook and basal structure components prepared as previously described[6]; samples 5, same as 4 and 6, except that no βME was added; sample 8, same as 2 and 7, except that no βMe was added. The letters in the centre refer to the position of some of the components of the basal structure that are found after the purified hook–basal structure[8] is dissociated. *a*, Component with apparent molecular weight of 60,000; *b*, hook subunit protein, *c* and c_1, positions assumed by component in the presence and absence of added βME; *d*, component with apparent molecular weight of 30,000; *e*, 27,000 molecular weight component.

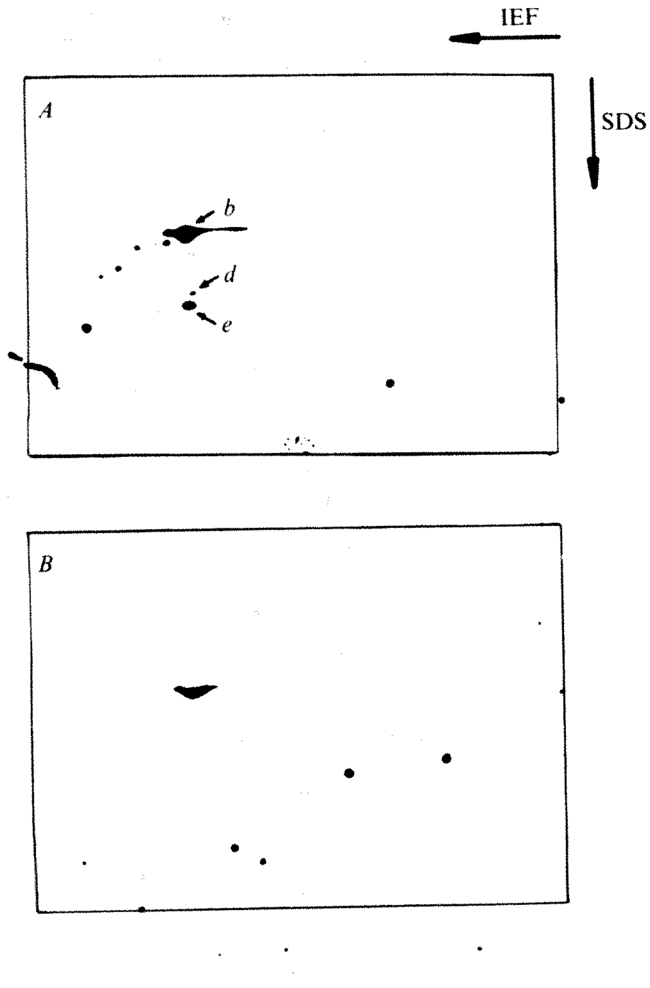
with hybrid *E. coli*–colicinogenic factor E_1 (Col E1) plasmids. Each hybrid carried a randomly selected fragment of *E. coli* DNA so that the bank, consisting of more than 2,000 clones, carried within it all the *E. coli* genes. Furthermore, each strain had an F factor which allowed the transfer of the hybrid plasmid. These strains were tested by mating into various *fla*⁻ recipients on motility plates. The clones that were able to transfer motility were further characterised by genetic complementation. Sixteen strains were found that carried plasmids with one or more of the known flagellar genes[12]. There were four in region I, seven in region II and five in region III. These strains were used to transfer the plasmids into a minicell-producing strain. Minicells were prepared[13] and purified by multiple sucrose gradients. The minicells were then incubated with ^{35}S-labelled methionine, and after incubation, the total minicell pellet was disassociated, and the peptides were separated by acrylamide gel electrophoresis. Different minicell preparations had different levels of contamination with whole cells. Contamination resulted in a low level of incorporation of label into a large variety of polypeptides. These formed very similar patterns of distribution on the gel, independent of the nature of the plasmid carried by the parent strain (Fig. 2, columns 1 and 2). On the other hand, there were specific, heavily labelled polypeptide bands that were characteristic of the hybrid plasmid carried by the minicells.

Thus far, minicells from strains that carried a plasmid with *fla* genes mapping in region III (pLC 24-16) were found to synthesise a polypeptide with the same mobility on acrylamide gels as flagellin. Plasmids that carried the *cheB* genes in region II (pLC 21-2 and pLC 24-15) directed the synthesis of polypeptides with the same electrophoretic mobility as the *cheB* gene products synthesised by hybrid *E. coli*–λ bacteriophage (our work, in preparation). Another plasmid carrying the *flaD* gene (pLC 7-18) led to the synthesis of distinctive polypeptides (Fig. 2, column 1) that have not yet been assigned to specific genes. Among the plasmids that have been tested, only those that carried genes in region I (pLC 11-15, pLC 36-11, pLC 24-46 and pLC 35-44) led to the synthesis of a band with the same electrophoretic mobility as the hook subunit (Fig. 2, column 2 and 4). In fact, four of the labelled bands *b*, *c*, *d* and *e* have the same mobilities as polypeptides derived from the purified hook–basal structure complex[8,14]. These bands correspond to molecular weights of 42,000, 38,000, 30,000 and 27,000.

To determine whether the band with a mobility corresponding to a molecular weight of 42,000 was the same as the hook subunit protein, a minicell extract was prepared and treated with anti-hook subunit antiserum. The precipitate was washed and separated by acrylamide gel electrophoresis. The major radioactive polypeptide found in the precipitate has the same mobility as the hook subunit (Fig. 2, column 3). The same experiment was performed using the two-dimensional isoelectric focusing technique described by O'Farrell[15]. Figure 3*A* shows that there are several different radioactive polypeptides. Spot *b* corresponds precisely with the position of nonradioactive hook subunit protein that was added to the mixture. After precipitation with specific antihook antibody, this spot was the only radioactive polypeptide found on the gel (Fig. 3*B*). In control experiments with heterologous antibody or with the specific antihook subunit antibody and extracts containing labelled proteins from different minicell preparations, no specific precipitation was found. Finally, in experiments using double diffusion in agar, the antihook subunit formed a specific line of precipitation only with the radioactively labelled material in extracts of minicells carrying the plasmids with genes in region I. Thus, the 42,000 molecular weight polypeptide synthesised in minicells carrying *fla* genes that map in region I behaves like the hook subunit protein.

Some of the other polypeptides that were synthesised in minicells carrying the region I plasmids were similar to other flagellar basal structure components. For example, the 38,000-molecular weight basal structure component had the distinctive property that its mobility on sodium dodecyl sulphate (SDS) gels was affected by the presence of β-mercaptoethanol (βME). In the presence of βME, its mobility corresponded to a molecular weight of 38,000 while in the absence of reducing agent, its mobility corresponded to a molecular weight of 36,000 (Fig. 2, column 6 and 5, bands *c* and c_1). The polypeptide synthesised in minicells behaved in the same way (Fig. 2, column 7 and 8, bands *c* and c_1). Furthermore, the 38,000 molecular weight component of flagellar basal structures is not found on the two-dimensional gels[6]. It is presumably lost during isoelectric focusing. The corresponding band in the minicell preparation also does not appear on two-dimensional gels (Fig. 3*A*). Finally, polypeptides *d* and *e* (Fig. 2 and Fig. 3*A*) have mobilities very similar to the basal structure components with molecular weights of 30,000 and 27,000 on two-dimensional gels[6].

Fig. 3 Autoradiograms of two-dimensional gels. Minicell extract for antibody precipitation was prepared as described in legend to Fig. 2 from minicells carrying pLC 11-15. The gel technique was that described by O'Farrell[16]. The left side of the gel is the acidic end of the isoelectric focusing run and the right side the basic end. *A*, whole extract before antibody precipitation; *B*, after antibody precipitation.



We conclude that a gene that maps in region I specifies the structure of the hook subunit protein. The polypeptide product of the gene carried on the hybrid plasmid was identified by its motility on one- and two-dimensional gels and by its specific precipitation with antihook subunit antiserum. Three other polypeptides with characteristics similar to the basal structure components with molecular weights of 38,000, 30,000 and 27,000 are also synthesised by the plasmid carrying genes in region I. This finding extends the approach previously described involving lambda-*E. coli* hybrids. It is now possible to identify all flagellar gene products by programming their synthesis with cloned fragments of *E. coli* DNA. Initial genetic studies on region I have identified three (*flaK, flaL, flaM*) flagellar specific complementation groups[16]. Further studies are required to define completely the genes in this region and to understand the regulatory mechanisms that control the expression of these genes and coordinate it with the other flagellar genes.

We thank Drs L. Clarke and J. Carbon for hybrid-plasmid-containing strains. This work was supported by a grant from the NSF. P.M. is a NRSA Postdoctoral Research Fellow of the NIGMS.

matters arising

Rock volatility and aerosol composition

GOLDBERG[1] has suggested the possible importance of contributions to the atmospheric burden of trace components from the sublimation of surface minerals. We show here, however, that the observed trace element concentrations could only be achieved by higher temperatures than those encountered on the Earth's surface. Goldberg used a simple kinetic model, where the rate of loss of substance per unit area φ from a pure surface under a vacuum is equivalent to the rate at which vapour molecules would reach the surface when the solid is in equilibrium with its vapour[2] and may be written

$$\varphi = p_0 \, (M/2\pi RT)^{\frac{1}{2}}$$

where p_0 is the equilibrium vapour pressure, M the molecular weight and R, T have their usual meanings. This represents the maximum rate at which molecules can leave the surface. In the presence of other gases, however, the rate will be lower owing to the existence of a boundary layer and transfer of vapour molecules across this layer will be the rate determining step in most cases. The rate of diffusion across a laminar boundary layer from 'Fick's Law' is

$$\varphi = \frac{DM}{RT} \frac{\partial p}{\partial x}$$

where D is the diffusion coefficient and x is distance. Trace component concentration in the atmosphere will be low as they are removed rapidly from the bulk atmosphere by convective and chemical processes, $(\partial p / \partial x)$ can be approximated by $p_0 / \Delta x$, where Δx is the thickness of the boundary layer (~ 2 mm) (ref. 3). The importance of the diffusion layer can be adequately demonstrated by the example of DDT ($M = 0.354$ kg) where $D = 5 \times 10^{-6}$ m^{2}s^{-1} and $p_0 = 2 \times 10^{-5}$ Pa (ref. 3). The value φ arising from a pure DDT surface is calculated as 7.3×10^{-12} kg m^{-2}s^{-1} which is in good agreement with the experimental rates (ref. 3) of 0.8–5.5 $\times 10^{-12}$ kg m^{-2} s^{-1}, but calculations using the simple kinetic model which neglects the boundary layer suggest rates some four orders of magnitude too high (9.6×10^{-8} kg m^{-2} s^{-1}).

When considering components of a mixed solid such as a mineral, the activity (f) of the component must be considered. Little is known about the activity coefficients applicable to the sublimation of trace components of minerals, but they can be of several orders of magnitude (for example, 10^{-3} to 10^3, ref. 4). In our model unit activity coefficients were assumed and activity was equated with mole fraction. A solid phase resistance to sublimation must also be considered. When a trace element evaporates from the exposed surface of a matrix, the surface region becomes depleted in the evaporating component. Thus the overall rate of loss may well be controlled by the replenishment of the surface region through transfer of the trace component to the surface from the bulk of the solid. Thus there may be two resistances to transfer, one in the solid phase and one in the gas phase, which limit the evaporative flux. Furthermore, solid phase resistance can also occur in pure solids where structural irregularities which control the sublimation must be regenerated[5]. For the minerals of interest here, the magnitude of the solid phase resistance is not easily determined and has been omitted. This yields upper limits to the sublimation rate as far as solid phase resistance is concerned.

When sublimation is the sole contribution to the atmospheric burden, the principle of steady state enables φ to be equated with the deposition rate per unit area CH/τ, where C is the atmospheric concentration, H is the height of the tropopause (about 13 km) and τ is the tropospheric residence time (about 10 d)[1]. Thus the pressure (p^*) needed to account for the observed atmospheric burdens can be calculated from

$$p^* = \frac{CHRT\Delta x}{DMf\tau} \quad (1 \text{ atm} = 10^5 \text{ Pa})$$

Table 1 Properties of some of the elements which behave anomalously in the atmosphere

Element	Atmospheric Concentration (from ref. 6) C (10^{-13} kg m^{-3})	Weight fraction of the crust (p.p.m.) (from ref. 8)	Mole fraction of crust ($\times 10^6$)†	p^* (10^{-6} atm)	T(°C)‡
SeO_2	2	0.05	0.03	4.7	77
As_2O_3	0.5	1.8	0.6	0.03	74
Sb_2O_3	0.3	0.2	0.04	0.18	198
PbO	35	12.5	3.6	0.32	600
CdO	2	0.2	0.1	1.0	680
Hg(1)	5	0.08	0.025	6.6	39

†Using average crustal compositions from ref. 8; the 'average' molecular weight of the crust was computed as 63.5 g mol^{-1}. Weight fractions were then corrected for relative molecular weight.

‡From p_0–T formulae, in ref. 9.

Table 1 shows the results of calculations using this formula for metals that show anomalously high atmospheric concentrations that cannot be accounted for by crustal or marine inputs. For most of the elements discussed here, vapour pressure data for actual crustal minerals is not available, so that measurements for pure solids as indicated are used for provisional estimates. The final column gives the minimum temperature at which the pressure p^* is achieved. For all the oxides, the calculated temperature is outside the range of validity of the p_0–T data. The direct extrapolation, however, overestimates the vapour pressure at a given temperature. It is noticeable that even for the volatile elements (As, Se, Sb) the oxides have insufficient volatility to account for their atmospheric levels at ambient temperatures, although temperatures of nearly 70 °C might be achieved at the surface of minerals in tropical regions. For CdO and PbO the temperatures required are well above ambient, but such temperatures may be achieved in a number of high temperature processes, such as ore roasting or coal burning and in volcanoes. The transfer of the more volatile elements to fly ashes has been noted[7]. As a special case the p^* and T have been calculated for mercury metal, with its high vapour pressure. As can be seen, a temperature of at least 39 °C is needed to account for the observed atmospheric levels if all the crustal burden of mercury existed as the liquid metal. Sublimation of natural mercury ores such as cinnabar (HgS) would, of course be very much slower. Further scrutiny of the p_0–T data indicates that activity coefficients of at least 10^4 and negligible solid phase resistance are needed to account for the anomolously high atmospheric concentrations of As, Se, Sb, Hg, Pb and

Cd by a sublimation mechanism at ambient temperatures. This is not to imply, however, that such processes could not be important at higher temperatures or lower atmospheric pressures, possibly contributing to the atmospheric chemistry of other planets.

Control of flight activity in mosquitoes

JONES, in his interpretation of the activity cycle of the mosquito *Culex pipiens fatigans* Wied. in constant light (LL) following a light : dark (LD) regime of 12 h light and 12 h dark[1], stated that it was possible to calculate that the first peak should have occurred about 18 h after light-on or 6 h after the normal time of light-off. In his recordings of activity the main peaks in LD 12:12 were immediately following light-off and light-on. In most field observations of biting activity[2–4], in the laboratory cycle of mating activity[5] and in my laboratory observations of flight activity, the main peaks in the daylength (LD 12:12) typical of the tropics are around midnight and after light-on. By plotting the positions of the peaks in various LD regimes I found the control of flight activity in *C.p. fatigans* to be a combination of light-on some 13–18 h earlier and light-off some 8–14 h earlier (Fig. 1). The mosquito will also respond immediately to light-on in LD 8:16 to LD 20:4. I did not study the activity in LL but in constant dark (DD) following an LD 12:12 I observed a bimodal cycle with one peak following light-on by about 18 h and the other following light-off by about 12 h; these were both repeated twice in DD with a period of about 27 h. Clear double peaks were shown in DD following an LD 4:20 rearing regime; the period in this case was about 24 h. The second peak became much greater with successive cycles to present a result resembling the activity in LL as recorded by Jones[1].

The separate phase-setting effects of light-on (dawn) and light-off (dusk) in a mosquito were first observed for *Aedes aegypti* L. and formed the basis for suggesting an association between the range of photoperiods in which these separate phase-setting effects reinforce each other and the photoperiod usually encountered by a species throughout its natural range[6]. For dark-active species, such as *Anopheles farauti* Laveran, the optimum photoperiod seems to be determined by the coincidence of a peak entrained by the previous light-off and the peak in response to light-on[7]. *C.p. fatigans*, to judge from the increase in the size of the light-off entrained peak in DD and LL, probably has the same mechanism for determining photoperiod. A theoretical optimum daylength of 12–14 h for *C.p. fatigans*, derived from Fig. 1. compares reasonably well with its known geographical range of 0°–35/40° latitude.

The relevance of the association between photoperiod measurement and the photoperiods within their natural geographical range is not obvious for tropical mosquitoes but, increasingly in recent years separate 'dawn' and 'dusk' oscillations have been linked with the measurement of photoperiod by insects which have a diapause stage in the annual life-cycle[8]. It has not been clearly established, however, whether overt rhythms of activity can be used as indicator rhythms in photoperiodism studies. I have studied several temperate species of mosquito which have at least two generations per year. For *C. pipiens pipiens* L. I obtained graphs of activity peaks which for adults reared in July from larvae collected in southern England (latitude 51 °N, daylength 15 h), that is, a summer generation, gave a theoretical optimum daylength range of 14–17 h, but for adults taken from hibernation in January, that is, the winter generation, the range was 11–12 h. *C. torrentium* Martini showed a range of 15–18 h for adults reared from larvae collected in mid-July whereas the range for adults reared from larvae collected in mid-September (daylength 13 h) was 12–14 h. The effect of shortening daylengths on summer generation mosquitoes and of lengthening daylengths on winter generation mosquitoes can clearly produce an imbalance between the internal mechanisms controlling flight activity, so there may be a link between overt flight activity rhythms and the photoperiodic mechanism controlling the adult diapause of hibernating mosquitoes.

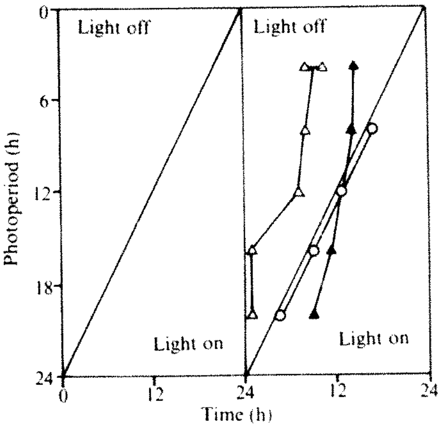

Fig. 1 The positions of the peaks of activity of *C.p. fatigans* relative to light-on and light-off when the mosquitoes are in different light regimes. Diagonal lines divide light-on and light-off periods. Peaks of activity are indicated as: ○, peak at light-on; △, peak following light-on by 13–18 h; ▲, peak following light-off by 8–14 h. Total of 26 individual females was studied; activity was recorded acoustically[6] at 25 °C; light intensity was 70 lx.

This work is part of a Ph.D thesis, Brunel University, 1969. I thank the Ministry of Overseas Development and the MRC for financial assistance and Professor J. D. Gillett for his interest and encouragement.

JONES REPLIES—Biting and mating depend on flight, but do not necessarily have to show the same pattern; all that is required is sufficient flight activity at the appropriate time. The cycle I have observed in *C.p. fatigans* provides such a permissive framework; it is also consistent with the pattern of flight activity measured in the field using window traps.

Taylor's results[1,2] could indicate an interesting difference in behaviour between strains (his material originated in Lagos). Confirmation of his results would be useful as the experiments he has quoted were all carried out at the same time using only one batch of insects which had been reared together.

'Dawn' and 'dusk' oscillators may indeed play an important part in the control of mosquito flight activity. This would fit in with the new model for circadian pacemakers proposed by Pittendrigh and Daan[3] which they describe as a 'clock for all seasons'.

Dirac's continuous creation cosmology and the temperature of the Earth

ROXBURGH[1] has contended that the present form of Dirac cosmology[2] predicts too low a temperature for the Earth (in the recent past) to be acceptable. He computed the time dependence of the temperature of the Earth with the relation

$$T = \left(\frac{L}{R^2}\right)^{1/4} \qquad (1)$$

The solar luminosity $L \sim G^7 \times M_\odot^5 \sim t^3$, when the Dirac prescriptions $G \sim t^{-1}$, $M_\odot \sim t^2$ are used. For the time dependence of the radius of the Earth R in atomic units, Roxburgh proposed and solved the equations of motion ((4) and (4*a*) in ref. 1). These equations are not valid in atomic units. Being the standard Newtonian equations, they are valid only in Einstein units where, since m is constant, the differentiation between (4) and (4*a*) in ref. 1 is meaningless. From Roxburgh's equations, we conclude that the orbital radius in Einstein units $\bar{R}$ = constant.

Dirac[1] has argued that with multiplicative creation, $R \sim \bar{R}t$. Equation (1) then yields $T \sim t^{1/4}$, as shown by Canuto and Lodenquai[3]. Such a time variation cannot be ruled out. While Roxburgh considers Dirac's argument unconvincing, we point out that it is substantiated by dynamic equations of a consistent theory (refs. 4 and 5). In the following, we indicate four equivalent methods by which the correct equation of motion in atomic units can be derived.

(1), With a general transformation of units of the form $d\bar{s} = \beta ds$, where $d\bar{s}$ and ds are the space-time intervals in Einstein and atomic units respectively, the geodesic equation of general relativity transforms into

$$\frac{d}{ds}(\beta v^\mu) + \beta\Gamma_{\nu\lambda}{}^{\mu}v^\nu v^\lambda = g^{\mu\nu}\beta_{\nu} \qquad (2)$$

(2) The gravitational field equations in atomic units given in refs 4 and 5 can be used to derive

$$T_{\mu,\nu}{}^{\nu} = -3\frac{\beta_{,\nu}}{\beta}\left(T_\mu{}^\nu - \frac{1}{3}T_\lambda{}^\lambda\delta_\mu{}^\nu\right) \qquad (3)$$

Using the stress-energy tensor of a pressureless fluid $T^{\mu\nu} = \rho v^\mu v^\nu$, equation (3) reduces to the generalised geodesic equation (2).

(3) in a gauge covariant theory of gravitation[4], the tensor equations in general relativity are replaced by co-tensor equations. The geodesic equation is replaced by

$$v^\nu v^\mu{}_{*\nu} = 0 \qquad (4)$$

where v^μ is now a co-vector of power -1 and * indicates co-covariant differentiation. It can be shown that equation (4) is a compact form of equation (2).

(4) Dirac[5] has given an action principle from which equation (2) can be derived.

With spherical symmetry, the Newtonian limit of equation (2) gives

$$\frac{d}{dt}(\beta\mathbf{r}) = -\beta\frac{GM_\odot}{r^2}\mathbf{r} \qquad (5)$$

This equation admits the angular momentum integral

$$\beta r^2\dot{\theta} = h = \text{constant} \qquad (6)$$

and therefore the reciprocal radius u satisfies the orbit equation

$$\frac{d^2u}{d\theta^2} + u = \beta^2\frac{GM}{h^2} \qquad (7)$$

Thus, the orbital radius R is given by

$$R \sim \frac{h^2}{GM_\odot\beta^2} \qquad (8)$$

In the gauge covariant theory with multiplicative creation as suggested by Dirac, it can be shown that $\beta \sim t^{-1}$. The result $R \sim t$ is thus confirmed.

There is abundant evidence to favour multiplicative creation over additive creation[3]. The gauge covariant theory is consistent with co-moving multiplicative creation. Roxburgh's suggestion of multiplicative creation at rest does not have a sound theoretical framework and his equation of motion for this case seems to be an *ad hoc* postulate, the consequences of which ought not to be associated with Dirac cosmology.

[5] Dirac, P. A. M. *Proc. R. Soc.* A333, 403 (1973).

ROXBURGH REPLIES—Canuto *et al.*[1] correctly point out that if the equations of motion in the Dirac[2] cosmology are Einstein's equations in Einstein units rather than in atomic units as I assumed[3], then the orbit of the Earth around the Sun increases in time $R_A \propto t$, so that the temperature on the Earth increases only slowly $T \propto t^{1/4}$. This is only the case if matter is created at rest relative to local matter, not if it is created at rest relative to the local cosmological rest frame. In this latter case, even if the equation of motion is Einstein's in Einstein units, we have for a system of $N(\tau)$ particles of mass $m(\tau)$

$$\frac{d}{d\tau}(Nmv) + NMv\frac{1}{N}\frac{dN}{d\tau} = -\frac{GMNm}{r^2{}_E} \qquad (1)$$

and with Nm = constant in Einstein units this gives

$$\frac{d}{d\tau}(Nv) = -\frac{GMN}{r^2{}_E} \qquad (2)$$

and hence $R_E \propto 1/N^2$. In atomic units $R_A \sim tr_E \propto t/N^2 \propto 1/t^3$ so the equilibrium temperature of the Earth satisfies

$$T_E \propto \left(\frac{L}{R_A}\right)^{1/4} \propto \left(\frac{G^7M^5}{R^2{}_A}\right)^{1/4} \propto t^{9/4} \qquad (3)$$

which predicts a temperature of about 180 K when the Earth was formed.

The assumption that Einstein's equations are valid in Einstein units, however, does not uniquely predict that the creation rate $\propto t^2$ or that the scale factor in cosmology is $S(t) \propto t$ in atomic units as in the Dirac model. Indeed, if we demand that there be no cosmological constant in Einstein units then one solution is clearly the Einstein de Sitter Universe with $S(t) \propto t^{2/3}$ in Einstein units. This is satisfied with the creation rate such that $N^\circ(\tau) \propto \tau^n$ for any n (my work, to be published). In atomic units this gives a scale factor

$$S(t) \propto t^{\frac{(3n+1)}{(3(n+1))}}$$

For $n = 0$ this is the classical Dirac cosmology $S \sim t^{1/3}$. The equilibrium temperature on the earth for this model then satisfies

$$T_E \propto t^{\frac{(n-5)}{(4(n+1))}} \qquad (4)$$

and is constant for $n = 5$. The point is that just to demand that Einstein's equations be valid in units in which mN, G, are constant does not determine the model, a whole family of models are possible that satisfy the large number hypothesis and Einstein's equations in suitable units, only if we demand that in atomic units $S(t) \sim t$, or equivalently that in Einstein units we have a static Einstein Universe, as we reproduce the Dirac model.

Devonian palaeogeography of Northern Britain

DONOVAN *et al.*[1] have recently summarised sedimentological data from the Devonian of North Scotland which they believe invalidate my suggestion of a large-scale sinistral shift along the Great Glen Fault (GGF) in late/post Devonian time[2–4]. Their main arguments are that "the ORS sediments of the Orcadian Basin on both sides of the GGF are very similar in character and show identical history of development" and that palaeocurrent vectors support sedimentation within a single basin. The authors consider the Orcadian Basin to have been of oval shape, the long axis being of the order of 400 km. If a basin of this size can have similar characteristics throughout there is no reason why the outcrops from a basin only about twice as long (corresponding to my proposed 500-km transcurrence) should not exhibit an equally good match of sedimentological and other features. The evolution of the Orcadian Basin may have been strongly linked with lateral and vertical movements of the GGF, causing simultaneous variation in sedimentary facies, tectonic structures and so on over extensive parts of its length. Furthermore, from the palaeocurrent vectors presented (dominantly from west of the fault) one can devise widely different reconstructions within the framework of a single basin: data from the adjoining shelf areas are very necessary before such information becomes relevant to the problem under consideration.

The available data can equally well be fitted to the model of the Orcadian Basin having subsequently become subdivided by a major transcurrent movement. With a 500-km sinistral displacement the East Shetland Basin, which includes thick basal breccias and coarse fluvial conglomerates derived from a metamorphic/plutonic terrain to the west[5], would fit in well with the geology of areas around southern Inverness-shire (west of the GGF).

Statement

IN September 1976 Dr Robert J. Gullis left our laboratory after having spent two postdoctoral years with us. He had been engaged mainly in measuring the levels of cyclic GMP in neuroblastoma cells and neuroblastoma × glioma hybrid cells. We published four papers on this matter together with him. After Dr Gullis had left, several of my colleagues (M. Brandt, J. Traber and D. van Calker) repeated this work, but were unable to reproduce it. Dr Gullis was therefore asked to return to our laboratory and repeat his essential experiments under supervision. During a 2-week period Dr Gullis carried out four series of experiments. After the experimental incubations, the samples were coded. In none of the experiments was Dr Gullis able to obtain his previous results. Neither morphine nor levorphanol nor the enkephalins nor cholinergic agonists changed the level of cyclic GMP in the hybrid cells.

In some of the publications listed below cyclic AMP was determined in the same samples in which cyclic GMP had been determined. The cyclic AMP assays were carried out by other members of the laboratory. But the printouts from the scintillation counter were left to Dr Gullis for evaluation.

Dr Gullis admitted having invented the results of all his experiments. Thus, I should like to let it be known to the scientific community that the following three publications are based on invented data:

Gullis, R. J., Traber, J. & Hamprecht, B. Morphine elevates levels of cyclic GMP in a neuroblastoma × glioma hybrid cell line. *Nature* **256**, 57–59 (1975).
Gullis, R. J., Traber, J., Fischer, K., Buchen, C. & Hamprecht, B. Effects of cholinergic agents and sodium ions on the levels of guanosine and adenosine 3′ : 5′-cyclic monophosphates in neuroblastoma and neuroblastoma × glioma hybrid cells. *FEBS Lett.* **59**, 74–79 (1975).
Gullis, R. J., Buchen, C., Moroder, L., Wünsch, E. & Hamprecht, B. Opiate-like effects of enkephalin on neuroblastoma × glioma hybrids, in *Opiates and endogenous opioid peptides* (ed. Kosterlitz, H. W.) 143–151 (Elsevier, Amsterdam, 1976).

The data on cyclic AMP were falsified by Dr Gullis in a fourth paper (Figs 3 and 4).
Brandt, M., Gullis, R. J., Fischer, K., Buchen, C., Hamprecht, B., Moroder, L. & Wünsch, E. Enkephalin regulates the levels of cyclic nucleotides in neuroblastoma × glioma hybrid cells. *Nature* **262**, 311–313 (1976).

B. HAMPRECHT
Max-Planck-Institut für Biochemie,
8033 Martinsried, FRG

DR GULLIS WRITES—I wish to disclose the fact that papers published in several journals with myself as principal author are not reliable. The curves and values published are mere figments of my imagination, and during my short research career I published my hypotheses rather than experimentally determined results. The reason was that I was so convinced of my ideas that I simply put them down on paper; it was not because of the tremendous importance of published papers to the career of a scientist.

Therefore I would like to let it be known that the following papers published while I was working in the laboratory of Dr B. Hamprecht are not reliable.

Gullis, R. J., Traber, J. & Hamprecht, B. *Nature* **256**, 57–59 (1975).
Gullis, R. J., Traber, J., Fischer, K., Buchen, C. & Hamprecht, B. *FEBS Lett.* **59**, 74–79 (1975).
Gullis, R. J., Buchen, C., Moroder, L., Wünsch, E. & Hamprecht, B. Opiate-like effects of enkephalin on neuroblastoma × glioma hybrids, in *Opiates and endogenous opioid peptides* (ed. Kosterlitz, H. W.) 143–151 (Elsevier, Amsterdam, 1976).

Another paper in which I was coauthor and submitted cyclic GMP values is also wrong in terms of the cyclic GMP content (Figs 3 and 4). The paper is

Brandt, M., Gullis, R. J., Fischer, K., Buchen, C., Hamprecht, B., Moroder, L. & Wünsch, E. *Nature* **262**, 311–313 (1976).

I would also like to disclose the fact that the following papers published with Dr C. E. Rowe are purely hypothesis.

Gullis, R. J. & Rowe, C. E. *Biochem. Soc. Trans.* **1**, 849 (1973); *Biochem. J.* **148**, 197–208; 557–565; 567–581 (1975); *J. Neurochem.* **26**, 1217–1230 (1976); *FEBS Lett.* **67**, 256–259 (1976).

This letter is to point out to the scientific community that the results presented in these papers are wrong and based purely on hypothesis. I must take full responsibility for these unfortunate incidents and have consequently suffered. I hope that my experiences are noted by others, and I would like to apologise to the scientific community and the various people involved.

R. J. GULLIS

A GUIDE TO RADIATION PROTECTION

J. Craig Robertson

A guide for the layman faced with the problems of dealing with radioactive materials during the course of his work. Assuming no previous scientific knowledge, the book discusses, amongst other things, different types of radioactive sources and how to shield the various radiations they emit.

COMPUTER SCIENCE AND TECHNOLOGY

Programming

A HANDBOOK OF SYSTEMS ANALYSIS

JOHN E. BINGHAM AND GARTH W. P. DAVIES

A practical guide to the design and use of systems for data collection and processing in the business situation.

hardcover £5.95

COMPUTING FOR ENGINEERS

R. T. FENNER

Complete FORTRAN programmes are presented, described and discussed in detail in this book, with an emphasis on good programming habits as well as thorough program testing. The book, which includes numerous illustrations and practical case studies, stresses the topics important to engineering computations not normally covered in programming manuals. Nearly all types of engineering problems likely to be encountered in undergraduate courses are described.

paperback £2.95

AN INTRODUCTION TO ALGOL 68 THROUGH PROBLEMS

A. LEARNER AND A. J. POWELL

Computer Science Series

CONSULTING EDITOR: PROFESSOR J. S. ROHL

This is the only available textbook on Algol 68. The subject is approached through a series of problems which are solved alogorithmically and step by step translated into logically structured programmes. The text includes complete programmes all of which have been checked by the authors. Illustrative exercises and a set of harder problems conclude each chapter.

paperback £2.25

MICROPROGRAMMING

GUY BOULAYE

EDITED BY DR. P. A. BEAVEN

A concise, lucid and low-priced introduction to microprogramming, intended as a textbook for undergraduate students of computer sciences, computer technology and digital electronic engineering. The structure and technology of computers is explained, but the core of the book is devoted to microinstructions and microprogramming.

hardcover £7.50 paperback £3.95

FINITE ELEMENT METHODS FOR ENGINEERS

R. T. FENNER

Intended as an introduction to finite element methods for engineering undergraduates, this book concentrates on the simplest methods suitable for solving two dimensional continuum mechanics problems, especially those encountered in stress analysis, fluid mechanics and heat transfer. Several practical case studies in mechanical engineering are described and solved in detail to serve as illustrations of the methods developed in the book.

hardcover £8.95 paperback £4.50

FUNDAMENTALS OF OPERATING SYSTEMS

A. M. LISTER

Computer Science Series

CONSULTING EDITOR: PROFESSOR J. S. ROHL

An introduction to the fundamentals of computer operating systems, emphasising the structural aspects of system design. Based on a course of lectures given to final year undergraduate students of computer science, it is suitable for those who have a basic grounding in computer science or equally for those who have worked with computers for some time.

hardcover £7.95 paperback £2.95

Technology

DIGITAL ELECTRONICS

F. DOKTER AND J. STEINHAUER

Philips Technical Library

This book provides a general survey of the whole field of digital techniques, opening with a systematic introduction to all topics of importance to the subject. Theoretical derivations are given where necessary for an understanding of the subject matter and each chapter contains specimen calculations and a discussion of practical problems.

hardcover £5.95

ELECTRONIC COUNTERS

R. M. M. OBERMAN

A comprehensive and wide ranging book which covers a vast number of different circuit counter designs. Some of the counters described are commercially available as single chip integrated circuits, others are designed to be used in digital integrated circuits. Since each chapter contains problems for solution and a bibliography, this book is suitable as a text at graduate level, but it will also be invaluable to designers of digital circuits.

hardcover £5.95

INTRODUCTION TO DIGITAL LOGIC

A. POTTON

Here is an up-to-date book which will help the student to grasp the basics of electronic digital systems as well as to develop the techniques necessary for the analysis and design of such systems. The author has here concentrated on practical design methods. Where a formal study of some area of theory is introduced, it is as an aid to design and analysis rather than as a purely academic study.

paperback £2.95

DIGITAL ELECTRONIC CIRCUITS & SYSTEMS

NOEL M. MORRIS

Macmillan Basis Books in Electronics

This textbook, written by a well-known author, is designed to cover all aspects of digital circuits and systems, from the basis of logic functions to a working system for an electronic calculator. It is based on modern technology, using the most up-to-date examples of digital electronics technology including integrated circuits and 7-segment display devices.

paperback £2.50

MAGNETIC BUBBLES

T. H. O'DELL

The *magnetic bubble* domain: the product of the latest research, can be used to build devices which are of great interest in electronics. The magnetic bubble is a mobile magnetic domain; that is a small region in a magnetic material which is magnetically saturated. The author has been careful to stress the practical applications of the research findings, as magnetic bubbles are bound to have a commercial future in the computer sciences and in telecommunications.

hardcover £8.50

SECURITY STANDARDS FOR DATA PROCESSING

SUSAN WOOLRIDGE, COLIN CORDER AND CLAUDE JOHNSON

Here is a book for all those who own, manage or program a computer, whether interested in appraising risks to problem solutions or those who have to deal with security procedures. Incorporating the latest tested security techniques from the United States and Britain, the emphasis is on practical measures for determining what risks exist and how much damage a computer installation is exposed to.

hardcover £4.95

M MACMILLAN PRESS

reviews

Human qualities and political realities

E. H. S. Burhop

Energy and Conflict: The Life and Times of Edward Teller. By S. A. Blumberg and G. Owens. Pp. xvii+492. (Putnam: New York, 1976.) $9.95.

THE role of physics in society has been transformed out of all recognition during the past fifty years. The demonstration that at least some of the discoveries of modern physics have immediate relevance for problems of human society has led inevitably to many aspects of physics research becoming inextricably linked with politics. Those physicists who aspire successfully to lead the work in such fields need not only the conventional gifts that make a great scientist—curiosity, creative imagination, enthusiasm, deep insight, critical scepticism and so on—but also a wide understanding of human and social problems and of political realities. This book describes how one such physicist met the challenge.

Edward Teller is one of a remarkable group of Hungarian-born emigrés (including Eugene Wigner, John von Neumann and Leo Szilard) who made great contributions to the development of nuclear energy in the USA. Teller had shown remarkable aptitude for research in theoretical atomic and nuclear physics and in theoretical chemistry, and his original contributions in these fields are very considerable. Unfortunately he was much less successful in dealing with the political problems to which I have referred, with the result that he has become a controversial figure, forfeiting the respect and friendship of many of the physicists whose good opinion he valued most and rightly or wrongly establishing for himself the image of a rather sinister Professor Strangelove figure to large sections of the public.

This biography of Teller traces his career through his early days as a student and brilliant young research physicist in Budapest, Germany and Copenhagen, his emigration to the USA, his involvement with the early work in neutron physics, and nuclear fission; and, throughout World War II and afterwards, his single-minded commitment to the realisation of a thermonuclear weapon, the so called superbomb. His campaign to secure agreement to a crash program to develop the hydrogen bomb brought him into conflict with many of his scientific-colleagues—especially Robert Oppenheimer, who had been in charge of the development of the wartime fission bomb at Los Alamos. Teller was given the green light to go ahead. In the cold war atmosphere of the time that produced the hysteria of McCarthyism, of which most of Teller's colleagues were thoroughly ashamed, Oppenheimer's opposition to the development of the hydrogen bomb was represented as something sinister, and Eisenhower ordered that Oppenheimer's security clearance should be subject to a hearing, as required by law, to show cause why it should not be rescinded. In the subsequent hearings before a specially constituted commission, Teller's evidence was decisive. The counsel for the Commission cross-examining Teller, put to him the key question "Do you or do you not believe that Dr Oppenheimer is a security risk?" Teller's reply included the damning words "I would like to see the vital interests of this country in hands which I understand better and therefore trust more".

This moment was a watershed in Teller's career. He has never been able to live it down. The Commission went on to remove Oppenheimer's clearance. Oppenheimer continued with his scientific work as Director of the Institute of Advanced Studies at Princeton. But he was a sensitive man and he never fully recovered from the ordeal through which he had had to pass.

Teller was given the opportunity to build up a new weapons laboratory at Livermore, California, in competition with the Los Alamos Laboratory, set up by Oppenheimer during the war, and was able to realise his ambition, which had become almost an obsession, to provide the US Army with its hydrogen bomb.

The story of the development of the hydrogen bomb is a fascinating one and both it, and the monumental clash between the personalities of Oppenheimer and Teller is well told. Both were equals as physicists but it would be hard to imagine two more different personalities. Oppenheimer was a man of great culture with very broad interests and understanding of social problems and their perspectives. Before the War he had identified the true nature of fascism and realised that only by building a popular front with all forces opposed to it, including the communists, could it be fought and defeated.

Teller was much more limited in his understanding of the broader problems of society. His attitudes were no doubt conditioned by his background and education in Hungary and Germany as the son of a prosperous Jewish lawyer. His family suffered discrimination under the Bela Kun regime of 1919 on account of their bourgeois origins. They witnessed the rise of anti-Semitism in Hungary during the period of the Horthy regime, eventually culminating in the unspeakable excesses against the Jews of the Nazi Arrow Cross Movement. He emerged with a simplistic, uncritical equation of Communism with Nazism and an irrational hatred of the Soviet Union which has undoubtedly coloured his judgment. While Oppenheimer looked beyond the era of the cold war with its "peace by mutual terror" to an era of negotiation, détente and "peace through understanding" which would make the qualitative escalation of nuclear weapons unnecessary, Teller apparently saw and still sees only the need for weapons escalation unlimited.

This book has no doubt been originally conceived as an apologia for Teller, to try to do something to restore his image. Nevertheless it is by no means an uncritical eulogy, and brings out some of the weaknesses as well as the favourable qualities of its subject. It seems to deal objectively with the clash of personalities between Oppenheimer and Teller, the highpoint of the narrative. Teller emerges from the book as a warm and friendly man and, to his credit, with a sincere detestation of secrecy in science. Yet, in the opinion of the reviewer, such desirable personal qualities cannot balance out the great harm his uncompromising hawkish attitudes have done to the prospects of building a peaceful and secure future for mankind. He represents an example and a warning of a very talented scientist with many laudable and human qualities, whose lack of understanding of the social and political forces at work in our society has been a misfortune for himself and his colleagues. ☐

Reproduction of eukaryotic cells

Reproduction of Eukaryotic Cells. By D. M. Prescott. Pp. ix+177. (Academic: New York and London, October, 1976.) $14.50;. £8.85.

ACCORDING to the blurb this book "integrates recent discoveries about the molecular biology of the cell cycle into a comprehensive explanation of cell reproduction". In his preface the author wisely states his purpose more modestly ". . . to organise into a single source the principal facts and observations on the cell life cycle . . . in an effort to increase our overall understanding of how these cells reproduce themselves and how this reproduction is regulated". The book interprets eukaryote cells to be mainly vertebrate derived, but we do get occasional forays into yeasts and amoeba. The monograph is intended to be (and indeed is) complementary to Mitchison's book, *Biology of the Cell Cycle* (Cambridge University: Cambridge and London, 1971), which dealt extensively with microorganisms.

After briefly introducing the cell cycle and discussing the pattern of cell mass increase between successive divisions the author plunges straight into cell synchronisation techniques. For many workers, cell synchrony is a prerequisite for any successful biochemical or molecular biological study of cell cycle control. The author does not make the usual mistake of ignoring the variability of G_1 but he seems puzzled by the failure of many attempts to achieve perfect cell synchrony. In spite of the 560 references (mostly we are told published since 1971), no mention is made of models of the cell cycle which not only predict that G_1 must of necessity be variable, but put this variation on a quantitative footing (Burns and Tannock, *Cell Tissue Kinet.*, **3**, 321, 1970; Smith and Martin, *Proc. natn. Acad. Sci. U.S.A.*, **70**, 1263, 1973). Whether these explanations of the variation of G_1 are accepted or not the variability of G_1 is an undeniable and unavoidable fact. As a consequence, temporal studies on the biochemistry of cell division are fraught with pitfalls. For instance, even within a mitotically synchronised population some cells enter S-phase within a few hours but other cells do not start DNA synthesis until many hours later. As a result, biochemical phenomena observed in an "early G_1" population are a mixture of events occurring in some cells just before DNA synthesis begins and events that occur in cells that will sit around for many hours before initiating S-phase. In "mid G_1" or "late G_1" the situation is worse. This unavoidable problem means that much of the biochemistry of G_1 is at best of questionable value and at worst useless. Synchronisation at other stages of the cell cycle is slightly more successful, but it is G_1 that is at the centre of cell proliferation control. A knowledge of what happens in G_1 will only come with a proper understanding of its variable nature and the nature of its variation. Until then even the best of monographs can throw little light on the subject.

Although those who have not been exposed to the cell cycle literature will find much of this book of interest, it is a pity that the author has drawn his brief so narrowly. The "molecular biology" we are promised on the dust-jacket turns out to be a rather dry series of studies with inhibitions of protein and RNA synthesis. There is nothing (for instance) on the role of microtubules in the formation of the mitotic spindle, little on the process of cytokinesis and very little (apart from a discussion of RNA and protein synthesis) about the process of mitosis itself. There is a chapter on that slumping commodity cyclic AMP but little indication of what interesting futures the author would invest in.

In short, although the book is a useful source of references about the bare essentials of the cell cycle it fails to convey much of the excitement which surrounds the study of cell division and its control. **Robert Shields**

Characteristic seeds

The Seeds of Dicotyledons. By E. J. H. Corner. Vol. 1: pp. ix+311; Vol. 2: pp. 552 (illustrations.) (Cambridge University; Cambridge, London and New York, 1976.) Vol. 1: £15; Vol. 2: £25.

THE flowering-plant taxonomist, struggling with a welter of data, may at times be forgiven for regarding Occam's razor as a more useful tool than the microtome. Not so his brother the phylogenist, for Nature has concealed the origins and ancestry of the angiosperms with such skill, that every scrap of evidence may be required to unravel the mystery, and transform hypothesis into proven fact. In this respect, seeds (surely of some significance in seed-plants) have been seriously underrated by taxonomists and phylogenists alike, perhaps because they are not the easiest things in the world to examine, or to describe.

Professor Corner claims that every natural family of dicotyledons has a characteristic seed, and that, in consequence, the classification of families into orders should be consistent with their seeds. To substantiate this claim 218 pages of volume 1 of *The Seeds of Dicotyledons* consist of brief (but perfectly ample) descriptions of seeds and ancillary structures from most dicotyledonous families, together with descriptions of the seeds of many genera within these families. Volume 2 furnishes the necessary illustrations, 647 plates in all, comprising what must amount to several thousand individual figures, each a clear *camera lucida* outline, the salient features emphasised by judicious stippling and shading. The amount of work involved in sectioning (free-hand) so much material at every stage of development from unfertilised ovule to ripe seed, and in illustrating the resultant observations, must have been stupendous, so that it is almost mean to suggest that the plates might have been even more useful had the individual figures and corresponding legends been more uniformly labelled with numbers or letters.

The phylogenetic conclusions which Professor Corner reaches as a result of his seed studies are (coming from the father of Durianology) not quite so startling as might have been supposed. All depends upon one's criteria of primitiveness. Professor Corner regards the elaborations of the Myristicaceous seed as the closest approximation to the primitive; thereafter it is but a step to the *Magnoliaceae, Annonaceae, Lauraceae* and *Monimiaceae*, and indeed to a situation which, through Hutchinson, Takhtajan and others, has become so familiar that we may well be too inclined to take it for granted. If so, the hypothesis that *Paeoniaceae, Cucurbitaceae* and *Convolvulaceae* belong to the same phyletic line; that *Grossulariaceae* should be allied to *Cruciferae* and *Polygalaceae*, and *Proteaceae* to *Papaveraceae* and *Fumariaceae* will jolt us out of complacency, and perhaps make us question (as Professor Corner anticipates) if "agreement in seed-structure should be employed to align such diverse plants in a phyletic series". I take his word for it that "it can stand enquiry". It is nonetheless surprising. **R. D. Meikle**
